ACKNOWLEDGEMENTS

I would like to thank all of the people who over the years have helped in the formation of this thesis. First, I would like to thank Dr. Hridesh Rajan for being a superb mentor over the last three years. His guidance, support, and encouragement throughout my entire research career and in writing this thesis have been a tremendous motivation. He has always insisted we read papers and constantly learn and the knowledge I have gained due to his support is tremendous. He has also provided funding for my research and travel to AOSD 2007 and OOPSLA 2008, which helped me gain a better perspective on how research is disseminated.

I would also like to thank Harish Narayanappa who spent much time and effort in helping me develop the initial versions of Nu. The initial implementations he helped develop were instrumental to this thesis. Thanks are also due to Rakesh Setty for helping proof-read earlier copies of this thesis. Over the years he has brought up several interesting problems related to my research and always asked questions to keep me on my toes.

I would like to thank my committee members Dr. Morris Chang and Dr. Vasant Honavar for their guidance and encouragement. I thank Dr. Gary Leavens for providing exceptional teaching during the early years of my research. His courses are one of the main reasons I decided to enter graduate studies. Additionally, I would like to thank the members of the Laboratory for Software Design for helping with proof-reading and various insights over the years.

Finally, I would like to thank my parents Mr. William Dyer and Mrs. Lois Dyer, and my loving girlfriend, Ms. Rose Sibbel. Without their support and encouragement I would not be where I am today.

ABSTRACT

Aspect-oriented programming techniques extend object-oriented programming with new methods to modularize concerns that otherwise would be non-modular. For example, logging concerns are typically scattered across a system but using aspect-oriented techniques they can be localized into a single high-level module. These techniques typically take modular high-level code and statically transform it into non-modular intermediate code.

The contribution of this work is the design and implementation of a flexible and dynamic intermediate-language (IL) model. The main motivation for the design of this IL model is to support a variety of dynamic aspect-oriented language constructs that are proposed in recent literature such as CaesarJ's deploy, history-based pointcuts, and control flow constructs. Our IL model provides a higher level of abstraction compared to traditional object-oriented ILs as a compilation target for such constructs, which makes it easier to provide efficient implementations of these constructs. We demonstrate these benefits by providing an industrial strength implementation for our IL model, by showing translation strategies from dynamic source-level constructs to our improved IL, and by analyzing the performance of the resulting IL code. Our evaluation using the SPEC JVM98 and Java Grande benchmarks shows that the overhead of supporting a dynamic deployment model can be reduced to as little as $\sim 1.5\%$, when compared to the unmodified VM.

CHAPTER 1. Introduction

Aspect-oriented programming (AOP) [24] techniques offer software designers improved methods to separate certain types of concerns in a system. For example, consider a thread pooling concern that returns a new thread from a previously allocated pool of threads. If this concern were added to an existing program, every call to allocate a new thread must be replaced with a call to the thread pool. These calls most likely are scattered throughout the program. Using AOP techniques, this change could be implemented in a modular fashion by using declarative constructs to identify thread creation and to replace those allocations with calls to the thread pool. The thread pooling concern is thus localized into a single module, allowing for easier evolution.

The declarative constructs to identify points where threads are created and replace them with calls to a thread pool are static AO constructs. These constructs can be statically composed with the original code to produce the desired result. Certain constructs have a more dynamic nature to them. For example, these constructs might rely on the dynamic control flow of a program and can't easily be statically composed with the original code, without requiring additional logic. These dynamic constructs have received a lot of attention in the past 3-4 years of aspect-oriented programming literature [2, 6, 7, 8, 15, 19, 20, 35, 36, 40, 41].

A number of use cases for dynamic AO constructs have also appeared e.g. in runtime monitoring, runtime adaptation to fix bugs or add features to long running applications, runtime update of dynamic policy changes, etc. Such use cases drive the need for more dynamic aspect-oriented (AO) language constructs. Consider for example a long-running web application that suddenly shows performance degradation while allocating threads. Using dynamic AO constructs, one could apply the thread pooling concern previously mentioned to temporarily solve the problem while investigating the underlying issue. Once the underlying issue is resolved, the thread pooling concern could be dynamically removed.

Some proposals for dynamic AO features have investigated support for these constructs by translating them to static constructs [9, 15, 40]. For example, Stolz and Bodden propose translating LTL formulas into AspectJ code [40]. This translation generates automata to check if formulas are satisfied, updating state for each proposition at certain points of the program using generated advice. At the points where state may change, the AspectJ code adds additional logic to update the automata and check the satisfiability of the formulas.

In some cases, a finer-grained deployment model enables simpler implementations e.g. in the case of temporal assertion checking using aspects, advice representing the following propositions need not be checked until the preceding, enabling proposition(s) are found true [10, 40]. Such translations demonstrate the need for a more flexible deployment model [8, 15]. In particular, the need to dynamically adapt the set of join points intercepted at a finer-grained level than currently available is demonstrated for existing dynamic constructs such as history-based pointcuts [10, 40] and cflow [9, 15].

1.1 Contributions

In this work, we propose an intermediate-language (IL) model that supports finer-grained runtime deployment at the level of advice-like constructs. The rationale for supporting such constructs at the intermediate-language level is to provide a higher level of abstraction as a compilation target for dynamic aspect-oriented language constructs, compared to object-oriented intermediate language models, thereby simplifying the support for such constructs. Such support at the intermediate-language level can be used as a building block for a variety of dynamic constructs in high-level aspect-oriented languages.

Our intermediate-language model, which we call *Nu*, extends the object-oriented intermediate-language model with two new atomic deployment primitives, *bind* and *remove*, and a point-in-time join point model [29]. The effect of these primitives is to manipulate *advising relationships*. For the purpose of this paper, by advising relationship we mean a many-to-one relation between join points and a delegate. If a point in the execution of a program and a delegate are in an advising relationship, the execution of the join point is extended by the delegate. The effect of the *bind* primitive is to dynamically create such an advising relationship. The effect of the *remove* primitive is to destroy an

advising relationship. Our intermediate-language model has the following properties:

- It is simple. Only two new primitives are added to the object-oriented intermediate-language model.
- It is flexible enough to be able to accommodate the requirements of a broad set of dynamic and static source language constructs such as AspectJ’s statically deployed *aspects* [23], CaesarJ’s *deploy* [30], control flow constructs such as AspectJ’s *cflow* and history-based pointcuts [2, 40].
- It provides a higher level of abstraction as a compilation target for dynamic aspect-oriented language constructs.
- It allows compilers to maintain the conceptual separation present in the source code in the object code as well. *Nu* supports what Bockisch et al. have called *structure-preserving compilation* [8]. The intermediate code now mirrors the design, which among other things is important for the efficiency of incremental compilers [7, 37] and dynamic adaptation.

An important consideration for such dynamic models is the performance overhead of supporting them. Previous research results have shown that support for such dynamic aspect-oriented models outside the virtual machine (VM) can be prohibitively expensive [6, 36]. Following Bockisch et al. [8], we argue that efficient support is possible for such constructs by utilizing extra information available inside the VM. To that end, we discuss strategies that contribute to near negligible overhead for *Nu*’s runtime flexibility.

In summary, this work makes the following contributions:

- a simple, flexible, and dynamic intermediate-language model;
- an implementation of the *Nu* model as an extension of the Sun Hotspot Java Virtual Machine (Hotspot JVM) [34], which serves to show the feasibility of supporting the proposed model in a production level virtual machine;
- a caching technique to reduce amortized join point dispatch overhead for dynamic deployment models;

- an implementation in a VM for the point-in-time join point model [29]; and,
- an analysis of techniques to optimize our highly dynamic deployment model.

In the following section, we describe our intermediate-language design. Our implementation strategy to support the *Nu* intermediate-language model in the Hotspot JVM is discussed in Section 3. A novel caching scheme is discussed in Section 4. We evaluate the performance of our VM in Section 5. Section 6 illustrates the potential utility of the intermediate-language design by showing strategies to support a variety of dynamic and static aspect-oriented constructs by translating them into our intermediate-language model. Section 7 discusses related work. Section 8 discusses future work and Section 9 concludes.

CHAPTER 2. Nu: A Dynamic AO IL Model

The key requirement for our IL model is to remain simple, yet flexible enough to be able to support both dynamic and static constructs in AO source languages. This section introduces the join point model adopted by our approach. We then illustrate new primitives using an example.

2.1 Nu’s Join Point Model

One central concept in common AO approaches is the notion of a join point. A join point is defined as a point in the execution of a program. For example, in AspectJ [23], the “execution of the method `Hello.main()`” in Figure 2.1 is an example of a join point. This join point may possibly occur at a location in the source code, popularly referred to as the *shadow* of the join point [17]. The shadow of the example join point is marked in Figure 2.1.

```
// Source Code
public class Hello {
    static void main(String[] arguments) {
        System.out.println("Hello");
    }
}

// Intermediate Code
static void main(java.lang.String[]);
/* AspectJ join point shadow for "execution of method Hello.main" starts here */
    getstatic      #2; //System.out
    ldc            #3; //String Hello
    invokevirtual  #4; //Method println
/* AspectJ join point shadow ends here */
    return
```

Figure 2.1 Illustration of the AspectJ Join Point Model

Instead of AspectJ’s join point model, we adopted a finer-grained join point model for *Nu*, proposed by Masuhara et al. [29]. Masuhara et al. call the join point model of AspectJ-like languages a *region-*

in-time model since a join point in these languages represents duration of an event, such as a call to a method until its termination. They propose a join point model called the *point-in-time* model in which a join point represents an instance of an event, such as the beginning of a method call or the termination of a method call [29]. They show that this model is sufficiently expressive to represent common advising scenarios.

In the point-in-time model, corresponding to AspectJ’s *execution* join point there are three join points: *execution*, *return*, and *throw*. Here, *throw* is when the executing method throws an exception. These three join points eliminate the need for three different types of advice: *before*, *after returning*, and *after throwing* advice. The *before execution*, *after returning execution*, and *after throwing execution* become equivalent to *execution*, *return*, and *throw* respectively. Figure 2.2 illustrates this model. Two join point shadows in the method `Hello.main()` are marked as being shadows for the join points “execution of the method `Hello.main()`” and “return of the method `Hello.main()`”. Similarly, corresponding to AspectJ’s *call* join point there are three join points: *call*, *reception*, and *failure*. Here, *failure* is when an exception is thrown by the callee.

```
static void main(java.lang.String[]);
/* Join point shadow for the join point "execution of the method Hello.main" */
    getstatic      #2; //System.out
    ldc           #3; //String Hello
    invokevirtual #4; //Method println
/* Join point shadow for the join point "return of the method Hello.main" */
    return
```

Figure 2.2 Illustration of the Point-In-Time Join Point Model [29]

At this time, *Nu* does not support *around* advice (see Section 8 for more details). Interested readers are referred to Masuhara et al.’s work [29] for more detail. We have also explicitly decided to not support static crosscutting mechanisms, such as inter-type declarations in AspectJ [23]. These constructs are largely static and they can be easily supported by high-level language compilers using static weaving techniques [11, 17].

Our adoption of this model was, in part, driven by the clarity it gives to the semantics of fine-grained dynamic deployment. One issue that arises with the deployment of dynamic aspects is when the aspect being deployed advises a join point that is already on the stack. With a region-in-time model,

	bind	remove
Stack Transition	..., Pattern, Delegate → ..., BindHandle	..., BindHandle → ...
Description	Associates the execution of all join points matched by Pattern to invoke Delegate	Eliminates the advising relationship represented by BindHandle
Exceptions	NullPointerException: thrown if any argument is null IllegalArgumentException: thrown if the stack is malformed	NullPointerException: thrown if the BindHandle is null IllegalArgumentException: thrown if the BindHandle is stale

Table 2.1 Specification of Primitives in *Nu*

it is not very clear whether this new aspect should advise the join point already on the stack and the problem is often left to the semantics of the virtual machine [22]. For example, assume that an aspect *a* is deployed during the execution of a method *m*. This aspect contains an after advice that intercepts the join point “execution of *m*”. Note that in the region-in-time model we are still in the scope of the join point “execution of *m*”. The question is whether to invoke *a* when *m* returns. Using a point-in-time model, this problem is avoided since a join point is never on the stack.

2.2 New Primitives: BIND and REMOVE

Our IL model adds only two primitives to the object-oriented IL: *bind* and *remove*. The informal specifications including stack transitions and exceptions that might be thrown are shown in Table 2.1. As described previously, the effect of these primitives is to manipulate what we call *advising relationships*.

An example is given in Figure 2.3. For ease of presentation, the corresponding high-level language code is shown. In this figure and in the rest of the presentation, special forms of **bind(..)** and **remove(..)** will be substituted where the intermediate-language primitives would normally appear. In the source code, a notation such as `id = bind(p, d)` represents generating two push instructions for the pattern *p* and the delegate *d* followed by generating the bind primitive, followed by a store instruction to store the result in *id*. Furthermore, **remove(id)** represents an instruction to push *id* on the stack followed by a remove primitive.

Figure 2.3 shows the code for **class** *AuthLogger*. The objective is to record the time of

```

public class AuthLogger {
    protected static BindHandle id = null;
    protected static Pattern loginPat;
    protected static Delegate logDel;
    static {
        /* create new Method and Execution objects */
        Method m = new Method("*.login");
        loginPat = new Execution(m);
        logDel = new Delegate(AuthLogger.class,
            AuthLogger.class.getMethod("log", new Class[0]));
    }
    public static void enable() {
        if (id == null)
            id = bind(loginPat, logDel);
    }
    public static void disable() {
        if (id != null) {
            remove(id);
            id = null;
        }
    }
    public static void log() {
        // record the time of login
    }
}

```

Figure 2.3 Bind and Remove in an Example Program

execution of any method named *login* in the system. Moreover, one should also be able to enable and disable the authentication logger during execution. To implement this logger, we need to specify the intention to select all methods with the name *login*. In the *Nu* model, one would create a pattern to represent this intention.

2.2.1 Patterns in Nu

A pattern is an object of type `Pattern`. It is created by instantiating a set of classes provided by the *Nu* standard library. It is first-class, in that it can be stored, passed as a parameter, and returned from methods. Like strings in Java, patterns are *immutable*; their values cannot be changed after they are created.

Table 2.2 shows some commonly used patterns available in our implementation. The basic patterns on the left (numbered 1–4) serve to select all join points (JPs) related to methods, constructors, fields, etc. For example, the pattern object returned by `new Method("*.login")` can be used to

Basic Patterns	Selected JPs	Filters	Selected JPs
1. Method	Method-related JPs	5. Execution	Method executions
2. Constructor	Constructor-related JPs	6. Return	Method returns
3. Initialization	Static initializer-related JPs	7. Throw	Method throws
4. Field	Field-related JPs	8. Call	Method calls
Patterns 5-10 take a pattern of type 1, 2, or 3 as argument. Patterns 11-12 take a pattern of type 4 as argument.		9. Reception	Method receptions
		10. Failure	Method failures
		11. Get	Field gets
		12. Set	Field sets

Table 2.2 Patterns Available in *Nu*'s Standard Library

select *execution*, *return*, *throw*, *call*, *reception*, and *failure* join points for all methods named “login”. The filter patterns on the right (numbered 5–12) expect one of the basic patterns as an argument and further narrow down the set of matching join points. For example, if we want to match the “execution of any method named login” we would have to first create the `Method` pattern discussed before. We would then pass this instance as an argument to the constructor of the `Execution` class. The resulting instance is the pattern for “execution of any method named login.” In the example shown in Figure 2.3, the static initializer of `class AuthLogger` creates this pattern and stores it in the static field `loginPat` so that it can be used for enabling the logger using the `bind` primitive.

2.2.2 The `bind` primitive

The `bind` primitive expects two values on the stack: a pattern (discussed previously) and a delegate. The delegate is a first-class, immutable object of type `Delegate`. Both these types are part of *Nu*'s standard library, which is an integral part of *Nu*'s virtual machine implementation. The pattern serves to select the subset of join points in the program. The delegate points to a method that provides the additional code that is to execute at these join points. Two exceptional conditions apply:

- If the top two items of the stack do not contain well-formed objects, i.e. a pattern and then a delegate, an exception of type `IllegalArgumentException` is thrown.
- Additionally, If either of the top two items of the stack are `null`, an exception of type `NullPointerException` is thrown.

In Figure 2.3, the static initializer of **class** `AuthLogger` creates a delegate to the method `AuthLogger.log()` and stores it in the static field `logDel` so that it can be used for enabling the logger using the bind primitive. The `enable()` method uses the bind primitive to create an advising relationship between the join points matched by the pattern `loginPat` and the delegate `logDel`, which enables logging of authentication attempts in the system. After the bind primitive finishes, the pattern and the delegate are popped off of the stack and a unique identifier, described in Section 2.2.3, is pushed on to the stack.

The bind primitive dynamically creates an advising relationship between the join points matched by the pattern and the supplied delegate. On completion of a bind, when a join point executes each delegate supplied with a pattern that matches that join point will intercept its execution. Delegates are invoked *in the same order* in which they were bound. Delegates are invoked at most once per join point (for reasons described in Section 6.3).

Future language extensions may allow ordering constructs; however, at this time we believe they are not necessary since compilers generating *Nu* intermediate code could re-order the bind calls (for example when modeling the static deployment model of AspectJ and implementing the *declare precedence* construct).

Upon completion of a call to bind, the delegate will intercept any join point that executes and matches the associated pattern. This behavior is intentional. Consider a tracing aspect, which will output a trace at the entry and exit of a method. If a bind primitive is used to enable the tracing, we want it to take effect immediately (thereby tracing the method exit of the method containing the bind primitive).

The language is defined with a per-thread semantics. This means that bind and remove primitives only affect advising relationships on the same thread that they were called from. This semantics is selected to avoid the need to make groups of bind/remove calls atomic (note, however, that individual calls are atomic). The termination of a thread causes all associations created by that thread to be automatically removed, since reaching a join point in the context of that thread is no longer possible.

2.2.3 Bind handles

The unique identifier returned by a bind primitive is an *immutable* object representing the advising relationship. This unique identifier is an object of *opaque* type `BindHandle`, which is also part of *Nu*'s standard library. A type is *opaque* if there is no way to find out its representation, even by printing. This identifier may only be created by the virtual machine.

2.2.4 The remove primitive

The remove primitive expects the unique, immutable identifier representing the advising relationship on the stack. It destroys the advising relationship corresponding to the identifier. An example is shown in Figure 2.3, where the `disable()` method uses the remove primitive to destroy the advising relationship corresponding to the `BindHandle` instance stored in the static field `id`, effectively ceasing logging.

If the supplied identifier is **null**, an exception of type `NullPointerException` is thrown. If the `BindHandle` instance is stale, i.e. if the advising relationship corresponding to the supplied identifier is already removed, an `IllegalArgumentException` is thrown.

CHAPTER 3. Prototype VM Implementation

We have extended the Sun Hotspot Java virtual machine (or Hotspot for short) to support the *bind* and *remove* primitives. In our prototype implementation, we mimic these instructions as native methods inside the VM. In the rest of this section, we describe the relevant aspects of Hotspot, our extensions, and a comparison of their runtime performance that serves to support our claim that it is feasible to support *Nu* in an industrial-strength VM implementation without significant performance degradation. In Section 3.4 we describe the dispatch at join points. Section 3.3 describes the implementation specific details for the *bind* and *remove* primitives. A novel caching mechanism is described in Section 4. Section 5 details our evaluation of the implementation.

3.1 Our VM Implementation Strategy

Hotspot uses mixed-mode execution for faster performance [1]. The key idea is that there are often no gains achieved by compiling the entire program to produce native code before running it [1, 34]. The compilation efforts are focussed on performance critical methods [34]. The insight is based on Hölzle and Ungar’s work on adaptive optimization of Self [21].

There are three modes of bytecode execution: an interpreter, a fast non-optimizing compiler and a slow optimizing compiler. Hotspot uses runtime profiling to identify a set of performance-critical methods in the Java program. For the parts that are performance critical, the adaptive optimizing compiler produces optimized native code.

Previous studies of Java programs, for example by Krintz et al. [26], show that up to 57% of the methods loaded by the VM are never executed. These studies, the results on adaptive optimization [21], and the highly dynamic nature of our intermediate-language model led us to our implementation strategy that normally we should dispatch advice using a method-dispatch table like strategy instead of

using bytecode rewriting and/or native code insertion and removal at join point shadows.

3.2 VM Implementation Overview

Figure 3.1 shows an overview of the components modified to implement the *Nu* virtual machine. The Hotspot interpreter was modified by adding additional assembly code for advice dispatch (JP Dispatcher). The standard Java Runtime Environment (JRE) has additional Java classes added to it for the *Nu* pattern library. The VM has additional C++ code added to handle *bind* and *remove* calls as well as perform pattern matching at join points. The caching mechanism described in Section 4 adds additional data to the `methodOop` class as well as a global counter. Additionally it adds code into the classloader to initialize the cache. More details about the caching mechanism are in Section 4.

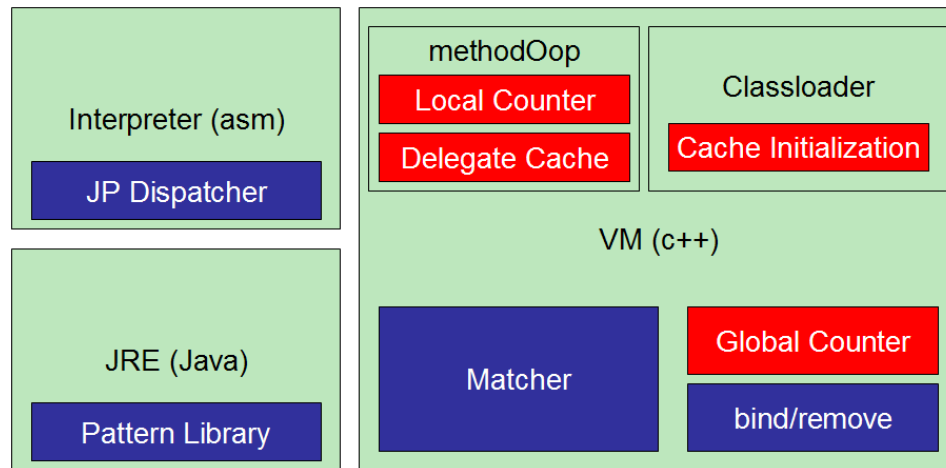

Figure 3.1 Overview of *Nu*'s VM Implementation

3.3 Handling Bind/Remove Calls in Nu's VM

The modified VM handles *bind* calls by storing the pattern and delegate objects into a list. There is one list for each type of join point and the pattern indicates which join point type(s) it applies to. It also performs some simple sanity checks (like verifying neither object are `null`, if the delegate is non-static then an instance object was passed in, etc). The VM then stores the pair into all applicable lists, generates and returns a unique `BindHandle` to the caller. The `BindHandle` is an instance of

the immutable Java class `BindHandle`, which may only be instantiated by the VM.

For *remove* calls, the modified VM simply removes the pattern/delegate pair matching the passed in `BindHandle` from all lists. Any join point that previously cached the delegate will lazily, on its next execution, recognize the cache is invalid and remove the delegate from its local cache.

The class file processor was modified to initialize data structures used at each join point. These data structures consist of several flags for use in caching, a local cached delegate list, and storage for the join point’s static reflective information (which is created lazily upon first use). The class file processor already accesses the bytecode of potential join point shadows, so no additional iterations were needed for initializing these data structures.

3.4 Advice Dispatch in Nu’s VM

Our current VM implementation provides an advice dispatch mechanism at each join point. The focus of the prototype presented in this paper is to optimize this dispatch mechanism. This mechanism handles matching the join point to existing patterns and invoking any corresponding matched delegates. We take advantage of the stub-generation code of Hotspot, adding in additional code to perform our advice dispatch.

The stub-generation code in Hotspot uses an assembler to generate generic stubs for the entry and exit of Java methods. These stubs include a check to see if a compiled version of the method exists and if so, directly jump to the compiled code. If not, the stub will continue executing inside the interpreter.

We inserted an advice dispatch mechanism in these stubs. Our advice dispatch mechanism performs three checks, implemented as three `mov`, three `cmpl`, and three `jcc` assembly instructions. These assembly instructions, shown in Figure 3.2, are directly emitted in the assembly code stubs generated by the VM.

The first check is a filtering check to prevent JRE and *Nu* runtime join point shadows from being advised.

The second check is a cache validation check that determines if the cached pattern-matching results for the join point shadow are valid. If the results are not valid, an incremental pattern match is performed for the join point shadow and the pattern-matching results are cached. Caching is described

```

    movl eax, methodOop.counter

// methodOop.counter == -1?
    cmpl eax, -1
// If yes, this JP is filtered
    jcc equals, ContinueJP

    movl ecx, globalCounter

// methodOop.counter == globalCounter?
    cmpl eax, ecx
// If yes, cache is valid
    jcc equals, InvokeDelegates

    call_VM incrementalMatcher

Figure 3.2 The advice dispatch assembly code

in detail in the next section.

The third check determines if there are any cached delegates that need to be invoked at this join point shadow, pending check of any dynamic residues. If the check passes, the delegates are invoked, otherwise the join point shadow execution continues. This code is designed to maximize the use of branch prediction algorithms implemented by most modern processors. If a join point is executed frequently, these checks will be optimized away by the (correct) branch prediction, minimizing the dispatch overhead.

CHAPTER 4. Caching technique in Nu's VM

Matching a join point with a list of bound patterns at runtime is an expensive operation that is a separate research topic on its own; however, caching techniques can be used to reduce the amortized cost of this operation. To that end, we have implemented a two-level caching algorithm for dynamic matching in our advice dispatch mechanism. Following the terminology of the computer architecture community, hereon we refer to these two caches as the *L1 cache* and *L2 cache*. A join point shadow match result being present or not present in a cache is referred to as a *hit* or *miss* respectively.

The L1 cache is maintained at the join point shadow in the form of a list of references to the (delegate, pattern) pairs that have already matched with that join point shadow. In the previous section, the cache validation check that we described pertains to the L1 cache. The L2 cache for each join point kind is maintained inside the pattern matcher in the form of a hash map from the join point shadow signatures to a list of current patterns that potentially match that signature. The L1 cache helps avoid calls to the incremental matcher. The L2 cache is inside the matcher and helps avoid duplicate matching. Similar to L1 and L2 caches inside a processor, a L1 hit is the least costly operation, followed by a L2 hit.

Cache Hit/Miss	Overhead of join point dispatch
L1 hit	Cost of equality test (local-bind-counter == global-bind-counter)
L2 hit	Incremental-Match(Join point, List of patterns)
L2 miss	Match(Join point, List of patterns)

Table 4.1 Cache Hits/Misses and Their Respective Costs

Our algorithm for detecting an L1 cache hit/miss is as follows. Each join point shadow contains a counter that is initialized to zero, when the class containing the join point shadow is loaded. There is also a global counter for each join point kind initialized to zero when the VM is initialized. The global

counter for a join point kind is incremented on *bind* / *remove* operations, if the bound / removed pattern may match that join point kind. Global counters are never decremented so that the local caches always know if they are current.

Patterns internally maintain the information about possible join point shadow kinds that may match during their construction using an iterative scheme. All patterns maintain a fast-match flag. All concrete patterns such as `Execution`, `Call`, etc, statically assign values to this flag that represent matching their specific join point shadow kinds. All dynamic patterns such as `This`, `Target`, etc, match selective join point kinds. When constructed, all `And/Or` composite patterns retrieve the fast match flags from inner patterns supplied as arguments to their constructors and set their own fast match flag to the logical `and/or` of their inner pattern's flag. This scheme is an adaptation of the fast-match technique used by the standard AspectJ compiler (ajc) during compilation [17].

At advice dispatch time, the check for L1 cache hit/miss is simply an equality test between the local counter for the join point shadow and the global counter for that join point kind. At join point match time, the local counter is reinitialized to the current value by the join point matcher. We suspect that better checking techniques might be possible; however, we were able to implement this check using two `mov`, one `cmpl`, and one `jcc` instruction and therefore we did not investigate further in this direction.

When a join point shadow incurs an L1 cache miss, the pattern matcher is called to perform incremental pattern matching. The overhead of calling the incremental pattern matcher is the cost of an L1 cache miss. The L2 cache is the incremental matcher and refers to a simple technique of only matching patterns that have not already been matched. The join point stores the *bindHandle* of the last pattern it was matched against. When an incremental match is performed, it only performs matching against patterns with newer *bindHandles*. The incremental match must also check the list of delegates in the L1 cache to verify none have been *removed* and if so they are taken out of the join point's L1 cache. At the end of the incremental match, the join point's L1 cache is set to valid, by setting the local counter in the L1 cache to the global counter's value and storing the last matched *bindHandle* in the L2 cache.

CHAPTER 5. Runtime Performance of Nu's VM

To evaluate the runtime performance of our implementation of *Nu*, we evaluated the performance of the system in the case where no *bind* calls have occurred to determine the join point dispatch overhead of our VM implementation. We used two standard Java benchmarks for our evaluation: SPEC JVM98 and Java Grande Framework (JGF). Since we are advocating modifying a production level VM, it is important that the modifications do not significantly affect the performance of existing applications. To measure the overhead in these cases, we ran the SPEC JVM98 and JGF method benchmarks with no *bind/remove* calls. We measured the performance of the unmodified JVM, our initial implementation of *Nu*, and our current implementation of *Nu* as described in this paper. All measurements were performed on a dual 2.2GHz XEON server with 2GB memory.

Figure 5.1 Comparison of Join Point Dispatch Times Using the JGF Benchmark (larger bars are better)

	JVM	Nu (initial)	% of JVM	Nu (current)	% of JVM
Same Instance	16.765E6	3.194E6	19.05%	16.105E6	96.06%
Same Sync. Instance	4.497E6	2.148E6	47.77%	4.518E6	100.45%
Same Final Instance	15.709E6	2.961E6	18.85%	15.537E6	98.90%
Same Class	16.032E6	2.801E6	17.47%	14.554E6	90.78%
Same Sync. Class	4.613E6	2.108E6	45.71%	4.457E6	96.63%
Other Instance	15.571E6	2.921E6	18.76%	15.055E6	96.68%
Other Abs. Instance	14.240E6	3.002E6	21.08%	15.181E6	106.61%
Other Class	15.449E6	2.817E6	18.24%	15.909E6	102.98%
Average	12.859E6	2.744E6	21.34%	12.664E6	98.48%

Table 5.1 Comparison of Join Point Dispatch Times Using the JGF Benchmark
(larger is better)

The results for the JGF method benchmarks are shown in Figure 5.1 and Table 5.1. Since the JGF method benchmark repeatedly executes simple methods to obtain the average number of method calls per second, this is where our caching implementation really shows up. Our initial version had to perform matching on each method call (even though there were no binds). With caching in place, this match is performed once. Our implementation went from 21.3% to 98.5% of the method calls achieved by the unmodified JVM.

The results for the SPEC JVM98 benchmark are shown in Figure 5.2 and Table 5.2. This benchmark measures the time to execute a set of realistic applications. These results were similar to the JGF benchmark. Our implementation went from a 37% execution time overhead to about 1.5% overhead.

	JVM	Nu (initial)	% of JVM	Nu (current)	% of JVM
check	0.052	0.052	100.90%	0.057	109.86%
compress	127.853	186.968	146.24%	129.068	100.95%
jess	28.086	48.199	171.61%	28.974	103.16%
db	66.346	66.915	100.86%	66.237	99.84%
javac	36.140	48.190	133.34%	36.636	101.37%
mpgaudio	105.596	130.548	123.63%	107.212	101.53%
mtrt	22.651	57.652	254.52%	23.812	105.13%
jack	24.188	26.556	109.79%	24.232	100.18%
Average	51.364	70.635	137.52%	52.028	101.29%

Table 5.2 Comparison of Join Point Dispatch Times Using the SPEC JVM98 Benchmark (smaller is better)

5.1 Cache Performance

To measure the penalty for a cache miss, we created a synthetic benchmark. This benchmark determined the baseline performance of calling a method (which has already had its cache initialized).

Figure 5.2 Comparison of Join Point Dispatch Times Using the SPEC JVM98 Benchmark (smaller bars are better)

It then creates a number of advising relationships which do not advise the method being measured. We then call the method and measure its performance. This process is then repeated 10,000 times and the results averaged. The results are shown in Table 5.3. Note that the measured performance indicates a linear relationship to the number of patterns already bound.

Number of Patterns	0	64	128	192	256
Time (μ s)	0.001	1.959	4.030	6.514	8.721

Table 5.3 Cache Benchmark Results

5.2 Bind/Remove Performance

To measure the performance of the *bind* and *remove* primitives, we created another synthetic benchmark. This benchmark contains one class with a method that will be matched by patterns in *bind* calls. The benchmark starts with an initial number of pattern/delegate pairs bound. This number was varied from 0 to 2048 and set in NUM. It then measures (separately) *bind* and *remove* calls and determines their averages. This benchmark was run 30 times for each value of NUM. The results showed that

performance for both primitives was independent of the number of existing advising relationships. The average time taken by the *bind* and *remove* primitives was $11\ \mu\text{s}$ and $3.4\ \mu\text{s}$ with a variance of approximately $3\ \mu\text{s}$ and $1\ E^{-4}\ \mu\text{s}$ respectively.

5.3 Delegate Invocation in Nu's VM

Due to the lack of delegates in Java, our initial implementation made use of the reflection API and Java Native Interface (JNI) methods. Users passed in strings representing the name of a class and the name of the delegate method and the runtime created a reflection `Method` object representing the specified delegate. This object was then passed into *bind* calls. JNI methods available inside the VM were then used to invoke the delegate where necessary.

Our current strategy still makes use of the reflection API `Method` class for passing in a delegate to *bind* calls. The *bind* implementation makes use of data structures already available inside the VM to keep track of information regarding the delegate, such as class, instance, method, etc. When the VM initially loads, template code for invoking delegates is generated inside the method stubs. This code makes use of the stored information about the delegate, avoiding the need to use expensive JNI methods.

Figure 5.3 Invoke Benchmark - Varying Number of Patterns

Figure 5.4 Invoke Benchmark - Varying % Matching Patterns

To measure the performance of our delegate invocation code, we created a benchmark that repeatedly calls a simple test method. A delegate method that increments a static counter is then used to create an advising relationship with our test method. A copy of the test method is created with manually inlined calls to the delegate method. The number of manually inlined calls is equal to the number of advising relationships created using *bind*. We then measure both copies of the test method (one with manually inlined calls and one with advising relationships to the delegate). A comparison to AspectJ's advice invocation code was not made, since most typical AspectJ compilers generate two methods at the call site (one to get an instance of the aspect and one to call the advice method). Figure 5.3 varies the total number of *bind* calls while keeping the percent that match the test method at 100%. Figure 5.4 varies the percentage of *bind* calls that match the test method while keeping the total number of *bind* calls at 256. As can be seen from the figures, our delegate invocation technique went from around 4% as efficient as the manually inlined version to around 82%. We believe that as we refine our technique, our invocation mechanism should approach relatively the same efficiency as manually inlining calls to delegate methods.

5.4 Summary

Our current prototype implementation serves as a proof of concept of our claim that support for the *Nu* IL model in production level virtual machines is feasible. Starting from our very inefficient implementation, we have improved our join point dispatch by reducing the overhead from 37% to 1.27% for the SPEC JVM98 benchmark and increased our performance on the JGF benchmark from 21.34% of the unmodified Hotspot to 98.48% of the unmodified Hotspot. Delegate invocation improved from around 4% as efficient as the manually inlined version to around 82% as efficient.

CHAPTER 6. Expressing AO Constructs in Nu

In this section, we describe strategies for compiling static and dynamic AO constructs to the *Nu* IL model. The rationale for this section is to demonstrate that the IL model is flexible enough to support static, dynamic, control flow, and history-based constructs in AO languages. Moreover, it also shows, by giving a translation, that compilation of these constructs generates modular object code, which is an additional benefit of the *Nu* model.

6.1 Compiling AspectJ Constructs

In this section, we demonstrate compilation strategies from AspectJ to the *Nu* IL model. The intention here is neither to discuss AspectJ in detail nor to compare the proposed approach with AspectJ. The intention here is to illustrate the potential utility of the *Nu* intermediate language model.

To illustrate the compilation strategies from AspectJ constructs to the *Nu* IL model, consider a simple extension of the Hello program shown in Figure 2.1. Let us assume that we were to write an aspect that would extend the functionality of the method `main()` so that instead of printing “Hello” it prints “Hello” followed by “World” on successive lines. An aspect `World` that implements this simple functionality is shown in Figure 6.1. The source code equivalent (for ease of presentation) of the *Nu* object code that will be generated for this aspect follows in Figure 6.2.

```
public aspect World {
    pointcut main(): execution(* Hello.main(..));
    after() returning: main() {
        System.out.println("World");
    }
}
```

Figure 6.1 The World Aspect

```

class World {
    static final World ajc$perSingletonInst = new World();
    static {
        /* create new Method and Execution objects */
        Method m = new Method("Hello.main");
        Execution e = new Execution(m);
        /* Delegate to the ajc$0 method */
        Delegate d = ... ;
        bind(e, d);
    }
    // Synthetic method generated for the advice
    void ajc$0() {
        System.out.println("World");
    }
    // Constructor World and helper methods hasAspect
    // and aspectOf elided for presentation purposes.
}

```

Figure 6.2 Compiling an AspectJ Aspect to *Nu* IL

6.1.1 Compiling Aspects, Pointcuts and Advice

Aspects are compiled into intermediate code units in the following way: pointcuts are compiled into pattern object instances, advice code is compiled into delegate methods, and bind primitives are generated in a static initializer of the aspect to associate the delegate code to the join points matched by the patterns. In the example shown in Figure 6.2, the generated object code for the method `ajc$0()` contains the advice code.

The generated intermediate code for the static initializer of **aspect** `World` contains additional code to first create an instance of the pattern `Method`. This instance is then used to create an instance of the pattern `Execution`. After creating the pattern instances, the delegate is created. The pattern and delegate instances are then used by the bind primitive to initiate join point interception.

An interesting property of the *Nu* version of the intermediate code for the aspect **class** `World` and the base **class** `Hello` (not shown) is that they remain separate in their own object code modules. Also, the object code for the base **class** `Hello` remains free of the aspect related intermediate code. This shows that *Nu* supports what Bockisch et al. have called *struture-preserving compilation* [8]. The intermediate code now mirrors the design, which among other things is important for the efficiency of incremental compilers [7, 37].

6.1.2 Compiling Complex Aspects

The illustrative AO application compiled in the previous section served to provide an example of a basic translation. To preserve the semantics of an aspect in the AspectJ language, compilation of an aspect in a real world AO application needs to account for two additional conditions: deployment as a single unit and whole program deployment of aspects.

First, aspects are deployed as a single unit at the beginning of the program. This requirement is addressed by generating all bind instructions for an aspect inside a transaction in the static initializer or in a synthetic static method `ajc$preClinit()`. A dummy reference to all aspects is inserted in the static initializer of the main application class as the first few instructions. This causes all aspects to initialize before the application execution begins. In the case of libraries containing aspects, a synthetic method could be generated and a requirement to call this function at initialization time could be imposed to initialize all aspects in the library.

A strategy similar to AspectJ's load-time weaving can also be used, where an XML file is generated by the compiler containing the details of all aspects in the system. All such aspects are then loaded by a custom class loader.

Second, aspects in AspectJ advise all threads in the program. In Java, when a thread is created it must be permanently bound to an object with a `run()` method. When the thread starts by calling `Thread.start()`, it will invoke the object's `run()` method. The strategy to deploy aspects for all threads in the program is to generate a set of instructions that execute between the methods `Thread.start()` and the object's `run()` method. These instructions are calls to the static method `ajc$preClinit()` on all aspects in the program. As mentioned previously, the bind instructions are generated in the `ajc$preClinit()` as a transaction. Executing this method deploys the aspects for the new thread.

6.2 AspectJ Constructs Performance

The performance of compiling AspectJ constructs to *Nu* IL was measured on the Java Grande method benchmarks. We measured four versions of a simple counting aspect: a version compiled with the standard AspectJ compiler (`ajc`), two versions compiled with the AspectBench compiler (`abc`) [3]

Figure 6.3 Performance Comparison of AspectJ Constructs on JGF Benchmarks (larger bars are better)

and a version using our compilation strategies to generate *Nu* IL. All versions ran in interpreted only mode, due to the *Nu* VM not currently supporting the Just-in-Time (JIT) compilation process.

ajc usually generates two method calls for an advice invocation, one to fetch an aspect instance and then the actual call to the advice method [17]. The idea behind this compilation strategy is that the JIT compiler can inline these calls. Unfortunately since we have to run in interpreted only mode, these inlining optimizations will never be performed by the VM.

In order to study the behavior as if the advice had been inlined, we made use of the AspectBench compiler, which has an option to enable advice inlining.

Figure 6.3 shows the results of the benchmarks. The *Nu* IL compiled code is faster than the AspectJ and non-inlined abc compiled code in all cases. The inlined abc version was slower in two cases and faster in the remaining cases. On average, it was only about 5% faster than the *Nu* IL version. This shows that even with the overhead shown in Figure 5.1, our implementation of the *Nu* IL model performs well for static AO constructs.

6.3 Compiling Control Flow Constructs

Our compilation strategy for the *cflow* and *cflowbelow* constructs is similar to the ideas presented by Hanenberg, Hirschfeld and Unland [15]. We will discuss the *cflowbelow* case as it is slightly more interesting, pointing out differences from *cflow* as necessary. Note that in addition to these compilation strategies, optimization strategies proposed by Avgustinov et al. [4] can also be applied.

Consider an example usage, where an **aspect** `Counting` uses the *cflowbelow* construct to count the number of calls to the method `Bit.Set()` below the control flow of the method `Word.Set()`. The pointcut expression will select all calls to the method `Bit.Set()` that occur between entry and exit of the method `Word.Set()`.

Our compilation strategy for the *cflow* and *cflowbelow* constructs is as follows: first, generate two new methods, say `Enter()` and `Exit()`, making sure that the names are unique in the class (since the class may already contain other methods), second, *bind* these two methods to execute at the entry and exit of the method `Word.Set()`, respectively, and third, generate code in `Enter()` and `Exit()` to *bind* and *remove* the code to the actual advice to execute whenever `Bit.Set()` is called. The stack `stack` is used to track multiple *bind* calls to `Word.Set()`, allowing the code to *remove* the proper association. Note that since a delegate is invoked at most once per join point, binding the same association relationship multiple times will not cause the VM to invoke the delegate multiple times at matching join point shadows.

Some bookkeeping is required to keep track of the execution stack depth in the variable `depth`. Inside the advice body, a check is generated to determine if the stack depth is the same. If the stack depth is the same, then any call being made to `Bit.Set()` is being performed from the initial call to `Word.Set()` — we are not *below* the control flow of `Word.Set()`. In this case, the delegate simply returns without executing the advice body. If the stack depth is larger, then we are below the control flow of `Word.Set()` and may continue executing the advice body. Figure 6.4 shows the results of the code generation for the example program described at the start of this section. As previously mentioned, the equivalent source code is shown for ease of presentation. The only difference between the compilation of *cflow* and *cflowbelow* is that the bookkeeping code for stack depth (highlighted in grey in Figure 6.4) is not generated in the case of *cflow*.

```

class Counting {
    static int count;
    static Call pat;
    static Delegate advice;
    static Stack<BindHandle> stack = ...;
    static int depth;
    static {
        pat = new Call(new Method("Bit.Set"));
        /* Delegate to the ajc$0 method */
        advice = ... ;
        /* Delegate to the Enter method */
        Delegate delBind = ... ;
        /* Delegate to the Exit method */
        Delegate delRemove = ... ;

        Method meth = new Method("Word.Set");
        Execution exec = new Execution(meth);
        Return ret = new Return(meth);
        Failure fail = new Failure(meth);

        bind(exec, delBind);
        bind(ret, delRemove);
        bind(fail, delRemove);
    }
    void Enter() {
        if (stack.Empty())
            depth = Thread.currentThread().countStackFrames();
        stack.push(bind(pat, advice));
    }
    void Exit() {
        remove(stack.pop());
    }
    void ajc$0() {
        if (depth >= Thread.currentThread().countStackFrames())
            return;
        count++;
    }
}

```

Figure 6.4 The Generated Code for *cflowbelow*

```

class Counting {
    static int count;
    static Call pat;
    static Delegate advice;
    static BindHandle id;
    static int depth;
    static int counter = 0;
    static { /* Same as previous impl.*/ }
    void Enter() {
        if (counter == 0) {
            id = bind(pat, advice);
            depth = Thread.currentThread().countStackFrames();
        }
        counter++;
    }
    void Exit() {
        counter--;
        if (counter == 0)
            remove(id);
    }
    void ajc$0() {
        /* Same as previous impl.*/
    }
}

```

Figure 6.5 Optimized Code for *cflowbelow*

A slightly more optimized version is shown in Figure 6.5. In this version, a counter is added to track if we are entering and exiting the initial call to `Word.Set()` instead of binding every time `Word.Set()` is called. While the performance of `bind` and `remove` calls was shown in Section 3 to be small, incrementing and decrementing a counter is significantly faster, as shown in the following section.

6.3.1 Control Flow Construct Performance

The performance of control flow constructs was measured on the JGF method benchmarks. Five versions were measured: a version compiled with AspectJ 1.5.3, two versions compiled with abc 1.3.0 at the lowest (O0) and highest (O3) optimization levels and both code generations shown in Figure 6.4 and Figure 6.5. Once again, all benchmarks were run in interpreted only mode.

The results are shown in Figure 6.6 and demonstrate that both of our compilation strategies fair well when compared to AspectJ and abc. Both approaches were on par with the highest level of optimization

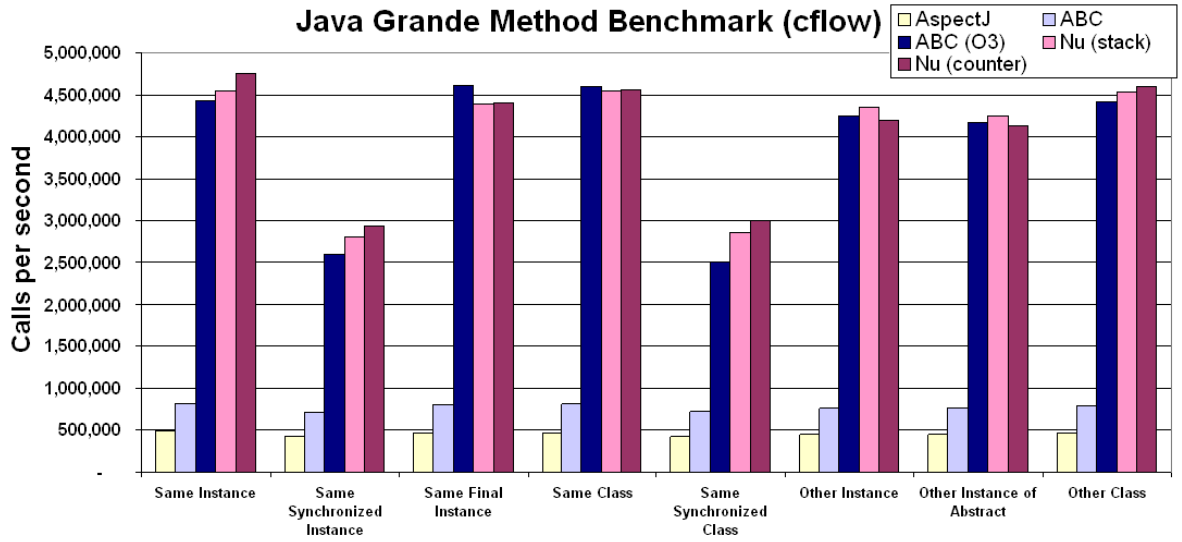

Figure 6.6 Performance Comparison of *cflow* Constructs using JGF Benchmarks (larger bars are better)

available in abc, which uses intra-procedural analysis.

6.4 Compiling Deployment Constructs

Some aspect languages such as CaesarJ [30] provide declarative constructs for dynamic deployment, e.g. `deploy` and `undeploy`, which are naturally supported by our primitives. Figure 6.7 shows a strategy for compiling such constructs.

The `deploy` and `undeploy` constructs are modeled by generating methods that contain the code to bind and remove the pointcuts and delegates in the aspect. The call to `deploy` and `undeploy` in the program is replaced by `World.aspectOf().deploy()` and `World.aspectOf().undeploy()` respectively.

The strategies discussed in Section 6.1.2 also apply in this case. This strategy for compiling dynamic deployment constructs also maintains the separation of the aspect modules and base modules.

```

class World {
    static World ajc$perSingletonInst = new World();
    static Pattern p = new Execution(new Method("*.main"));
    /* Delegate to the ajc$0 method */
    static Delegate d = ... ;
    static BindHandle id = null;
    void deploy() {
        if (id == null)
            id = bind(p, d);
    }
    void undeploy() {
        if (id != null) {
            remove(id);
            id = null;
        }
    }
    void ajc$0() {
        System.out.println("World");
    }
    // Elided generated code for hasAspect() and aspectOf() helper methods
}

```

Figure 6.7 Compiling Dynamic Deployment Constructs

6.5 Compiling Temporal Constructs

Stolz and Bodden proposed a runtime verification framework, where the static aspect deployment model is utilized to verify properties expressed as linear temporal logic formula over pointcuts [40, 40]. These properties are predicates over program traces, and have also been called history-based pointcuts. Among others Douence et al. [12], Bockisch, Mezini and Ostermann [9], Walker and Viggers [42], and Allan et al. [2] have argued for aspect language constructs of similar flavor. An example of such a temporal property is

$$G(\text{call}(*\text{Word.set}(\cdot)) \rightarrow F(\text{call}(*\text{Bit.set}(\cdot))))$$

which means that every call to the method `Word.set()` is finally followed by a call to the method `Bit.set()`. This property contains two propositions, call to the method `Word.set()` and call to the method `Bit.set()`. For checking such a property, Stolz and Bodden [40, 40] create aspects that contain state variables representing the fact that a proposition has been satisfied. For each proposition (pointcut), an advice would be created that manipulates the state variables in the aspect. The advice and state variables together serve to model the state machine. Figure 6.8 shows the aspect for our example,

based on Stolz and Bodden's example [40, Fig 3.].

```

aspect Tcheck {
  pointcut p1(): call(* Word.set(..));
  pointcut p2(): call(* Bit.set(..));
  int p1 = 1; int p2 = 2;
  Formula state = Globally(Implies(p1, Finally(p2)));
  Set<int> propSet = new Set<int>();
  after() : p1() { propSet.add(p1); }
  after() : p2() { propSet.add(p2); }
  after() : p1() || p2() {
    state = state.transition(propSet);
    if (state.equals(Formula.TT)) { /* report formula as satisfied*/ }
    else if (state.equals(Formula.FF)) { /* report formula as falsified*/ }
    state.clear(); //reset proposition vector
  }
}

```

Figure 6.8 Temporal Property Checking Aspect Based on [40]

A version of the temporal aspect in *Nu* IL model is shown in Figure 6.9. First, patterns are created to model pointcuts and delegates to the methods are created. The first pattern and delegate is used for the one-time *bind* on line 12 in Figure 6.9. The bind handle received from this *bind* is not stored to allow for optimizations. The effect of the one-time *bind* is that `afterP1()` starts intercepting the join points matched by `call(* Word.set(..))`, which represents the first proposition in the temporal formula. Once the first proposition is true, i.e. the method `afterP1()` executes, besides managing the logic as before, a check for the second proposition is inserted into the system. This is achieved by the *bind* on line 19 in Figure 6.9. When the second proposition is satisfied, the method `afterP2()` executes, which besides managing the logic as before, stops the check for the second proposition as it is no longer necessary.

To use Hanenberg et al.'s terminology [15], *Nu*'s version of the **aspect** Tcheck affects only the initial set of join points selected by the the pointcut `call(* Word.set(..))`. After the advice on line 18 executes, it morphs to include the join points selected by the pointcut `call(* Bit.set(..))`. As Bodden and Stolz pointed out, dynamically (un)deploying portions of the temporal matching infrastructure in this manner can lead to improved runtime performance [10].

```

1 class Tcheck {
2   static BindHandle id = null;
3   static Pattern prop2;
4   static Delegate d2;
5   int p1 = 1; int p2 = 2;
6   Formula state = Globally(Implies(p1, Finally(p2)));
7   Set<int> propSet = new Set<int>();
8   static {
9     Pattern prop1 = new Call(new Method("Word.Set"));
10    prop2 = new Call(new Method("Bit.Set"));

12    /* Delegate to the Tcheck.afterP1 method */
13    Delegate d1 = ... ;
14    /* Delegate to the Tcheck.afterP2 method */
15    d2 = ... ;

17    bind(prop1, d1);
18  }
19  void afterP1() {
20    propSet.add(p1);
21    if (id == null)
22      id = bind(prop2, d2);
23    afterP1P2();
24  }
25  void afterP2() {
26    propSet.add(p2);
27    remove(id);
28    id = null;
29    afterP1P2();
30  }
31  void afterP1P2() {
32    state = state.transition(propSet);
33    if (state.equals(Formula.TT)) {
34      // report formula as satisfied
35    } else if (state.equals(Formula.FF)) {
36      // report formula as falsified
37    }
38    state.clear(); // reset prop vector
39  }
40 }

```

Figure 6.9 Nu's Version of the Tcheck Aspect

6.5.1 Temporal Construct Performance

The performance of temporal constructs was measured on the Java Grande method benchmarks. The same framework and formula were used for both the AspectJ and *Nu* versions. Once again, all benchmarks were run in interpreted only mode. The results are shown in Figure 6.10. Once again, the *Nu* IL version performed similarly to the AspectJ version.

Figure 6.10 Performance Comparison of AspectJ and *Nu* Versions of Temporal Constructs (larger bars are better)

CHAPTER 7. Related Work

Three closely related and complimentary research ideas are run-time weaving, load-time weaving and virtual-machine support for AOP. We discuss these ideas in detail below.

7.1 Run- and Load-Time Weaving

There are several approaches for run-time weaving such as PROSE [36], Handi-Wrap [6], Eos [38, 39], etc. A typical approach to runtime weaving is to attach hooks at all join points in the program at compile-time. The aspects can then use these hooks to attach and detach advice at run-time. An alternative approach is to attach hooks only at potentially interesting join points. In the former case, aspects can use all possible join points, excluding those that are created dynamically so the system will be more flexible. The disadvantage is the high overhead of unnecessary hooks. In the latter case, only those aspects that utilize existing hooks can be deployed at run-time, but the overhead will be minimal for a runtime approach.

Eos uses the second model, i.e. only instrument the join points that may potentially be needed. Handi-Wrap uses the first model, making all join points available through wrappers. PROSE indirectly uses the first model, exposing all join points through the debugger interface. PROSE allows aspects to be loaded dynamically without restarting the system. An additional advantage of indirectly exposing join points through a debugger interface is that new join points (created by reflection) are registered automatically. As observed by Popovici et al. [36] and Ortin et al. [32], however, performance in both cases is a problem.

A load-time weaving approach delays weaving of crosscutting concerns until the class loader loads the class file and defines it to the VM [28]. Load-time weaving approaches typically provide weaving information in the form of XML directives or annotations. The aspect weaver then revises the assem-

blies or classes according to weaving directives at load-time. A custom class loader is often needed for this approach. There are load-time weaving approaches for both Java and the .NET framework. For example, AspectJ [23] has load-time weaving support. Weave.NET [27] uses a similar approach for the .NET framework. The JMangler framework can also be used for load-time weaving [25]. It provides mechanisms to plug-in class-loaders into the JVM.

A benefit of the load- and run-time weaving approaches is that they delay weaving of AO programs. A contribution of our approach might also be perceived as delaying weaving, however, we view the interface and corresponding contracts between the language designs and execution model designs as a larger contribution of our work. The decoupling between language compilers and the virtual machine achieved by the interface provided by our IL model enables independent research in these areas. Simpler aspect language designs and compiler implementations might be realized without spending significant time on the optimization of the underlying AO execution models. Novel optimization mechanisms for the underlying execution models can be developed independent of the language design as long as it conforms to the interface. The load-time weaving approaches do not provide these benefits.

The bind and remove primitives are similar to install and uninstall messages in AspectS [18]. The difference is that install and uninstall messages are sent to aspects in AspectS, whereas bind and remove can be thought of as messages sent to the virtual machine.

7.2 Virtual-Machine Support of Aspects

Steamloom [8] and *PROSE2* [35] both aim to achieve an aspect-aware Java VM, to enhance the runtime performance of AOP. *Steamloom* extends the Jikes Research VM, an open source Java VM [5]. Traditional approaches for supporting dynamic crosscutting involve weaving aspects into the program at compilation. *Steamloom* moves weaving into the VM, which allows preserving the original structure of the code after compilation and shows performance improvements of 2.4 to 4 times when compared to AspectJ. It accomplishes this by modifying the Type Information Block to point methods to a stub that modifies the existing byte code to weave in the advice. On the other hand, *PROSE2* proposes an enhanced implementation for the original *PROSE* approach, by incorporating an execution monitor for join points into the virtual machine. This execution monitor is responsible for notifying the AOP engine

which in turn executes the corresponding advice.

Steamloom has support for deploying (and undeploying) aspects as a unit. *Nu*'s model allows for a finer-grained level of deployment. Aspects in *Nu* can be deployed in whole, or in part due to the lower-level abstractions provided by the intermediate-language primitives. This functionality would need to be simulated in Steamloom using conditional pointcuts.

Haupt and Schippers propose a delegation-based machine model [16] for AOP support that uses proxy objects and delegation chains to add/remove additional functionality as needed. This model could be considered an implementation of Ossher's proposed machine model based on fragmented objects [33]. Both the delegation-based model and *Nu*'s model aim to be targets for high-level AOP languages, however, the implementation of *Nu* focuses on efficiency and production-level VM support. The delegation-based model is slightly more flexible due to its support of introductions, which is future work for the *Nu* model.

Golbeck et al. propose lightweight support in virtual machines for AspectJ [14]. A modified version of the Jikes research virtual machine reads annotations generated by the standard AspectJ compiler (ajc) to provide additional support for the woven aspects in the form of generating more optimized machine code. The virtual machine itself does not perform any advice weaving and thus the language model is quite different from that of *Nu*. Their approach shows potential performance benefits for programs written with AspectJ while our approach tries to be general enough to support multiple high-level languages. Note that both approaches allow execution of AspectJ code compiled with a standard AspectJ compiler.

CHAPTER 8. Future Work

Our future investigations will focus on two key areas: language extensions and virtual machine optimizations.

8.1 Language Extensions

Our current implementation does not support *around* constructs in AspectJ-like languages. Masuhara et al. have proposed adding two constructs, *proceed* and *skip*, to handle around advice [29]. We plan to add and implement similar constructs in our IL model to explore support for around advice in our pointcut model.

Currently, our intermediate-language design does not support inter-type declarations. These constructs allow aspects to declare new methods or fields in another type, declare a type extends a new class, or declare a type implements new interfaces. Inter-type declarations can be compiled to the *Nu* intermediate language by directly adding the declarations to the class that it crosscuts. In cases where the declaration affects more than one class, this will require compiling several classes. Clearly, this strategy is not modular since a change in an aspect may affect not only the aspect's object code, but also the object code of each class into which the inter-type declaration is being introduced.

A more general problem is support for multi-dimensional separation of concerns and HyperJ constructs in the virtual machine. Fortunately, researchers are beginning to identify possible directions. For example, recently Ossher [33] identified a runtime model based on fragmented objects as a basis, which appears to be a promising direction for future extensions of the *Nu* model.

8.2 Optimizations

We have planned several optimizations to further decrease the dispatch time of our prototype VM. Additional optimizations for improved pattern matching and delegate invocation are also planned. In the rest of this section, we will briefly describe these and other optimizations.

8.2.1 Further Improved Join Point Dispatch

The Hotspot VM keeps a list of tables for efficient dispatch. During VM initialization time, this table is initialized with code buffers that contain optimized code for various different types of entry and exit events. In our current implementation, we insert additional instructions into these code buffers. During the execution of a program, an entry and exit is translated to jumps to different entries in these tables as appropriate.

We plan to implement strategies to swap entries in this table such that an entry always points to the most optimal code buffer. At VM initialization time, we will generate multiple generic code buffers, each optimized for specific advice dispatch scenarios. For example, if we have not seen any bind instructions yet for a join point kind, there is no need for advice dispatch condition checks. As soon as the VM sees a bind call for a specific join point kind, it checks to see if the entry table is already initialized to support dispatch of that join point kind. If not, it replaces the entry with the right code buffer. These modified entries will not be generated for every join point instance, just for each join point kind. On a remove, the VM will check to see if there are any more binds remaining in the list of a join point kind. If there are no more binds in a list of join point kinds, the entry for that join point kind is replaced with the original entry that does not contain advice dispatch checks. These two modifications should further speed up the join point dispatch by eliminating the need for redundant checks.

We also plan to investigate using existing frameworks inside Hotspot to detect frequently dispatched advice. This advice could then be inlined using either byte code reweaving or natively using Hotspot's JIT compilers. Hotspot's de-optimization framework could possibly be used to remove previously inlined advice.

8.2.2 More Efficient Join Point Matching

The language implementation techniques for aspect-oriented quantification mechanisms, i.e. matching join points against a (possibly large) set of pointcut predicates, have not received much attention. This is primarily because most aspect-oriented approaches today employ compile-time deployment of aspects, where the cost of quantification is a small percentage of total compilation time. Recently, however, many use cases for dynamic aspect deployment have emerged [6, 8, 35, 36].

An implementation challenge for languages providing dynamic deployment constructs is to efficiently determine the set of join points that are matched by the aspect being deployed (or removed). This is primarily because in this case the cost of matching may become a significant portion of the cost of the deployment operation.

In the future, we will look into efficient join point matching mechanisms. One direction is a decision tree-based approach for matching join points against a set of pointcuts[13]. Unlike previous approaches implemented in AO compilers that treat each pointcut individually, one can maintain all pointcuts in the system in a single decision tree, which allows us to utilize more implication relationships resulting in a faster matching process.

8.2.3 Additional Identified Optimizations

Since patterns are first-class objects available in the high-level language, they are re-usable. This allows for possible optimizations by compilers, such as locating commonly used sub-patterns that can be created once and re-used.

Additionally, since patterns are immutable, a virtual machine that implements the *Nu* model needs not worry about a pattern instance changing after creation, which allows for the following optimizations inside the virtual machine.

When a pattern is created, a mirror native (C++) object can be created inside the virtual machine that will be much faster to access for pattern matching purposes, compared to accessing Java objects. By making patterns immutable, we eliminate the requirement to maintain the consistency between the pattern and its mirror C++ object.

For patterns that use regular expressions, at the time of their creation a deterministic finite-state

automaton can be created and stored in the mirror native object for faster matching [31]. By making patterns immutable, we once again eliminate the requirement to maintain the consistency between the regular expression contained inside the pattern and its mirror deterministic finite state automaton contained inside the C++ object. A similar strategy is feasible for bind handles, where the internal representation of the bind handle can also be mirrored as a C++ object. The representation of the opaque Java object can contain a pointer to its mirror C++ object and vice-versa.

During a remove, the pointer in the Java object corresponding to the bind handle can be redirected to `null`, marking the bind handle as *stale*. This will allow for an easy check for stale bind handles. Note that, if a stale bind handle is supplied to the remove primitive, an exception of type `IllegalArgumentException` is thrown.

Additionally, the C++ objects for bind handles can be allocated on a separate, small heap ignored by the standard garbage collector. Instead, a specialized and very fast garbage collector can be run more often on this heap, which will traverse the C++ object to Java object link to check if the Java object representing the bind handle has fallen out of scope. In other words, it will compute whether the Java object for the bind handle can be garbage collected. If so, this means that the advising relationship corresponding to that bind handle will never be removed in the thread's life-time because the semantics of the remove primitive requires the original bind handle. Such advising relationships can be safely optimized using advice inlining techniques similar to those used by Steamloom [7, 8], which have shown to have comparable performance to static-weaving approaches.

This optimization is likely to be helpful for static deployment of aspects. If the generated intermediate code for statically deployed aspects does not store the bind handle returned by the bind primitive, the bind handle is eligible for garbage collection immediately after bind completes. Recognizing the opportunity for such optimization allows the *Nu* model to remain flexible in general, but offer comparable performance in cases where limited power is needed.

CHAPTER 9. Conclusion

In this paper, we introduced *Nu*, an AO IL model that adds two primitives to object-oriented IL models. These primitives are geared towards a class of AO languages called pointcut-advice languages. *Nu* is motivated by the need to provide a richer compilation target for dynamic constructs compared to object-oriented intermediate-languages. We illustrated that a variety of AO language constructs such as static, dynamic, control flow, and trace-based can be expressed in terms of the *Nu* model. An additional benefit that we observed was that representation of these constructs in *Nu* preserved the AO design modularity in the object code.

We also described a prototype virtual machine implementation that supports the *Nu* IL model. Our performance analysis showed that there is negligible performance degradation of method dispatch time compared to the unmodified JVM. The speed of invoking the delegate also remains fairly close to the manually in-lined method call because of our caching mechanisms.

Our work can also be viewed as a proposal to establish an interface and corresponding contracts between language designs and execution model designs. This interface decouples language compilers and the virtual machine potentially enabling independent research in these areas. Simpler aspect language designs and compiler implementations might be realized without spending significant time on the optimization of the underlying AO execution models. Novel optimization mechanisms for the underlying execution models can be developed independent of the language design as long as they conform to the interface. Moreover, the effect of such optimization techniques is likely to benefit all such language implementations; hence, the perceived benefit of improvements is likely to be greater.
