ABSTRACT

Increasingly larger number of software systems today are including data science components for descriptive, predictive, and prescriptive analytics. The collection of data science stages from acquisition, to cleaning/curation, to modeling, and so on are referred to as *data science pipelines*. To facilitate research and practice on data science pipelines, it is essential to understand their nature. What are the typical stages of a data science pipeline? How are they connected? Do the pipelines differ in the theoretical representations and that in the practice? Today we do not fully understand these architectural characteristics of data science pipelines. In this work, we present a three-pronged comprehensive study to answer this for the state-of-the-art, data science in-the-small, and data science in-the-large. Our study analyzes three datasets: a collection of 71 proposals for data science pipelines and related concepts in *theory*, a collection of over 105 implementations of curated data science pipelines from Kaggle competitions to understand data science *in-the-small*, and a collection of 21 mature data science projects from GitHub to understand data science *in-the-large*. Our study has led to three representations of data science pipelines that capture the essence of our subjects in theory, in-the-small, and in-the-large.

CCS CONCEPTS

• **Software and its engineering** → **Software creation and management**; • **Computing methodologies** → **Machine learning**.

1 INTRODUCTION

Data science processes, also called *data science stages* as in stages of a pipeline, for descriptive, predictive, and prescriptive analytics are becoming integral components of many software systems today. The data science stages are organized into a *data science pipeline*,

where data might flow from one stage in the pipeline to the next. These data science stages generally perform different tasks such as data acquisition, data preparation, storage, feature engineering, modeling, training, evaluation of the machine learning model, etc. In order to design and build software systems with data science stages effectively, we must understand the structure of the data science pipelines. Previous work [20, 67] has shown that understanding the structure and patterns used in existing systems and literature can help build better systems. In this work, we have taken the first step to understand the structure and patterns of DS pipelines. Fortunately, we have a number of instances in both the state-of-the-art and practice to draw observations. In the literature, there have been a number of proposals to organize data science pipelines. We call such proposals *DS pipelines in theory*. Another source of information is Kaggle, a widely known platform for data scientists to host and participate in data science competitions, share datasets, machine learning models, and code. Kaggle contains a large number of data science pipelines, but these pipelines are typically developed by a single data scientist as small standalone programs. We call such instances *DS Pipelines in-the-small*. The third source of DS pipelines are mature data science projects on GitHub developed by teams, suitable for use by others. We call such instances *DS Pipelines in-the-large*.

This work presents a study of DS pipelines in theory, in-the-small, and in-the-large. We studied 71 different proposals for DS pipelines and related concepts from the literature. We also studied 105 instances of DS pipelines from Kaggle. Finally, we studied 21 matured open-source data science projects from GitHub. For both Kaggle and GitHub, we selected projects that make use of Python to ease comparative analysis. In each setting, we answer the following overarching questions.

- (1) **Representative pipeline:** What are the stages in DS pipeline and how frequently they appear?
- (2) **Organization:** How are the pipeline stages organized?
- (3) **Characteristics:** What are the characteristics of the pipelines in a setting and how does that compare with the others?

This work attempts to inform the terminology and practice for designing DS pipeline. We found that DS pipelines differ significantly in terms of detailed structures and patterns among theory, in-the-small, and in-the-large. Specifically, a number of stages are absent in-the-small, and the DS pipelines have a more linear structure with an emphasis on data exploration. Out of the 11 stages seen in theory, only six stages are present in pipeline in-the-small, namely *data collection*, *data preparation*, *modeling*, *training*, *evaluation*, and *prediction*. In addition, pipelines in-the-small do not have clear separation between stages which makes the maintenance harder. On the other hand, the DS pipelines in-the-large

have a more complex structure with feedback loops compared to the theoretical representations. *Data preprocessing, training, and modeling* stages are prevalent in the filenames and modules of the large projects, whereas other stages are occurring without explicitly mentioning them in the software architecture. Moreover, we identified different pipeline patterns followed in specific phase (development/post-development) of the large DS projects.

We contributed three representations of DS pipelines that capture the essence of our subjects in theory, in-the-small, and in-the-large that would facilitate building new DS systems. We anticipate our results to inform design decisions made by the data pipeline architects, practitioners, and software engineering teams. Our results will also help the DS researchers and developers to identify whether the pipeline is missing any important stage or feedback loops (e.g., *storage* and *evaluation* are missed in many pipelines).

The rest of this article is organized as follows: in section §2, we describe our study of DS pipelines in theory. Section §3 describes our study of DS pipelines in-the-small. Section §4 describes our study of DS pipelines in-the-large. In Section §5, we describe the threats to the validity, section §6 describes related work, and section §7 concludes.

2 DS PIPELINE IN THEORY

Data Science. Data Science (DS) is a broad area that brings together computational understanding, inferential thinking, and the knowledge of the application area. Wing [77] argues that DS studies how to extract value out of data. However, the value of data and extraction process depends on the application and context. DS includes a broad set of traditional disciplines such as data management, data infrastructure building, data-intensive algorithm development, AI (machine learning and deep learning), etc., and covers both the fundamental and practical perspectives from computer science, mathematics, statistics, and domain-specific knowledge [9, 70]. DS also incorporates the business, organization, policy and privacy issues of data and data-related processes. Any DS project involves three main stages: data collection and preparation, analysis and modeling, and finally deployment [76]. DS is also more than statistics or data mining since it incorporates understanding of data and its pattern, developing important questions and answering them, and communicating results [70].

Data Science Pipeline. The term *pipeline* was introduced by Garlan with *box-and-line* diagrams and explanatory prose that assist software developers to design and describe complex systems so that the software becomes intelligible [23]. Shaw and Garlan have provided the *pipes-and-filter* design pattern that involves stages with processing units (filters) and ordered connections (pipes) [67]. They also argued that pipeline gives proper semantics and vocabulary which helps to describe the concerns, constraints, relationship between the sub-systems, and overall computational paradigm [23, 67]. By *data science pipeline* (DS pipeline), we are referring to a series of processing *stages* that interact with data, usually acquisition, management, analysis, and reasoning [46, 47]. The sequential DS stages from acquisition, to cleaning/curation, to modeling, and so on are referred to as *data science pipeline*. A DS pipeline may consist of several stages and connections between them. The stages are defined to perform particular tasks and connected to other stage(s) with

input-output relations [4]. However, the definitions of the stages are not consistent across studies in the literature. The terminology vary depending on the application context and focus.

Different study in the literature presented DS pipeline based on their context and desiderata. No study has been conducted to unify the notions DS pipeline and collect the concepts [65]. While designing a new DS pipeline [78], dividing roles in DS teams [39], defining software process in data-intensive setting [75], identifying best practices in AI and modularizing DS components [4], it is important to understand the current state of the DS pipeline, its variations and different stages. To understand the DS pipelines and compare them, we collected the available pipelines from the literature and conducted an empirical study to unify the stages with their subtasks. Then we created a representative DS pipeline with the definitions of the stages. Next, we present the methodology and results of our analysis of DS pipelines in theory.

2.1 Methodology

2.1.1 Collecting Data Science Pipelines. We searched for the studies published in the literature and popular press that describes DS pipelines. We considered the studies that described both end-to-end DS pipeline or a partial DS pipeline specific to a context. First, we searched for peer-reviewed papers published in the last decade i.e., from 2010 to 2020. We searched the terms “*data science pipeline*”, “*machine learning pipeline*”, “*big data lifecycle*”, “*deep learning workflow*”, and the permutation of these keywords in IEEE Xplore, ACM Digital Library and Google Scholar. From a large pool, we selected 1,566 papers that fall broadly in the area of computer science, software engineering and data science. Then we analyzed each article in this pool to select the ones that propose or describe a DS pipeline. We found many papers in this collection use the terms (e.g., machine learning lifecycle, etc.), but do not contain a DS pipeline. We selected the ones that contain DS pipeline and extracted the pipelines (screenshot/description) as evidence from the article. The extracted raw pipelines are available in the artifact accompanied by this paper [5]. Thus, we found 46 DS pipelines that were published in the last decade.

Besides peer-reviewed papers, by searching the keywords on web, we collected the DS pipelines from US patent, industry blogs (e.g., Microsoft, GoogleCloud, IBM blogs), and popular press published between 2010 and 2020. After manual inspection, we found 25 DS pipelines from this grey literature. Thus, we collected 71 subjects (46 from peer reviewed articles and 25 from grey literature) that contain DS pipeline. We used an open-coding method to analyze these DS pipelines in theory [5].

2.1.2 Labeling Data Science Pipelines. In the collected references, DS pipeline is defined with a set of stages (*data acquisition, data preparation, modeling, etc.*) and connections among them. Each stage in the pipeline is defined for performing a specific task and connected to other stages. However, not all the studies depict DS pipelines with the same set of stages and connections. The studies use different terminologies for defining the stages depending on the context. To be able to compare the pipelines, we had to understand the definitions and transform them into a canonical form. For a given DS pipeline, identifying their stages and mapping them to a canonical form is often challenging. The sub-tasks, overall goal of

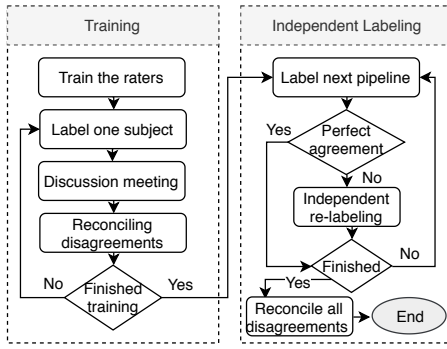

Figure 1: Labeling method for DS pipelines in theory

the project, utilities affect the understanding of the pipeline stages. To counter these challenges, we used an open-coding method to label the stages of the pipelines.

Two authors labeled the collected DS pipelines into different criteria. Each author read the article, understood the pipeline, identified the stages, and labeled them. In each iteration, the raters labeled 10% of the subjects (7-8 pipelines). The first 8 subjects were used for training and forming the initial labels. After each iteration, we calculated the Cohen’s Kappa coefficient [73], identified the mismatches, and resolved them in the presence of a moderator, who is another author. Thus, we found the representative DS pipeline after rigorous discussions among the raters and the moderator. The methodology of this open-coding procedure is shown in Figure 1. The entire labeling process was divided into two phases: 1) training, and 2) independent labeling.

Training: The two raters were trained on the goal of this project and their roles. We randomly selected eight subjects for training. First, the raters and the moderator had discussions on three subjects and identified the stages in their DS pipeline. Thus, we formed the commonly occurred stages and their definitions, which were updated through the entire labeling and reconciliation process later. After the initial discussion and training, the raters were given the already created definitions of the stages and one pipeline from the remaining five for training. The raters labeled this pipeline independently. After labeling the pipeline, we calculated the agreement and conducted a discussion session among the raters and the moderator. In this session, we reconciled the disagreements and updated the labels with the definitions. We continued the training session until we got perfect agreement independently. The inter-rater agreement was calculated using Cohen’s Kappa coefficient [73]. A higher κ ([0, 1]) indicates a better agreement. The interpretation of κ is shown in Figure 2a. In the discussion meetings, the raters discussed each label (both agreed and disagreed ones) with the other rater and moderator, argued for the disagreed ones and reconciled them. In this way, we came up with most of the stages and a representative terminology for each stage including the sub-tasks.

Independent labeling: After completing the training session, the rest of the subjects were labeled independently by the raters. The raters labeled the remaining 63 labels: 7 subjects (10%) in each of the 9 iterations. The distribution of κ after each independent labeling iteration is shown in Figure 2b. In each iteration, first, the

Range (κ)	Agreement level	Iteration #	κ	Iteration #	κ
0.00 - 0.20	Slight agreement	1	0.67	6	0.91
0.21 - 0.40	Fair agreement	2	0.74	7	0.87
0.41 - 0.60	Moderate agreement	3	0.82	8	0.90
0.61 - 0.80	Substantial agreement	4	0.84	9	0.94
0.81 - 1.00	Perfect agreement	5	0.84	10	0.91

(a) Interpretation of Kappa (κ) (b) Agreement in different stages
Figure 2: Labeling agreement calculation

raters had the labeling session, and then the raters and moderator had the reconciliation session.

Labeling. The raters labeled separately so that their labels were private, and they did not discuss while labeling. The raters identified the stages and connections between them, and finally labeled whether the DS pipeline involves processes related to cyber, physical or human component in it. In independent labeling, we found almost perfect agreement ($\kappa = 0.83$) on average. Even after high agreement, there were very few disagreements in the labels, which were reconciled after each iteration.

Reconciling. Reconciliation happened for each label for the subject studies in the training session, and the disagreed labels for the studies in independent labeling session. In training session, the reconciliation was done in discussion meetings among the raters and the moderator, whereas for the independent labels, reconciliation was done by the moderator after separate meetings with the two raters. For reconciliation, the raters described their arguments for the mislabeled stages. For a few cases, we had a straightforward solution to go for one label and abort the other. For others, both the raters had good arguments for their labels, and we had to decide on that label by updating the stages in the definition of the pipeline. All the labeled pipelines from the subjects are shared in our paper artifact [5].

Furthermore, after finishing labeling the pipelines stages, we also classified the subject references into four classes based on the overall purpose of the article. First, after a few discussions, the raters and moderator came up with the classes. Then, the raters classified each pipeline into one class. We found disagreements in 6 out of 71 references, which the moderator reconciled with separate meetings with the two raters. Based on our labeling, the literature that we collected are divided into four classes: describe or propose DS pipeline, survey or review, DS optimization, and introduce new method or application. Next, we are going to discuss the result of analyzing the DS pipelines in theory.

2.2 Representative Pipeline in Theory

The labeled pipelines¹ with their stages are visually illustrated in the artifact [5].

RQ1a: What is a representative definition of the DS pipeline in theory? From the empirical study, we created a representative rendition of DS pipeline with 3 layers, 11 stages and possible connections between stages as shown in Figure 3. Each shaded box represents a DS stage that performs certain sub-tasks (listed under the box). In the preprocessing layer, the stages are *data acquisition*, *preparation*, and *storage*. The algorithmic steps and data processing are done in the model building layer. Post-processing layer includes the tasks that take place after the results have been generated. The DS pipeline stages are described in Figure 4.

¹<https://github.com/anonymous-authors/DS-Pipeline/blob/main/pipelines.pdf>

Figure 3: Concepts in a data science pipeline. The sub-tasks of the stages are listed below each stage. The stages are connected with feedback loops denoted with arrows. Solid arrows are always present in the lifecycle, while the dashed arrows are optional.

Stages of Data Science Pipeline
Data Acquisition (ACQ): In the beginning of DS pipeline, data are collected from appropriate sources. Data can be acquired manually or automatically. Data acquisition also involves understanding the nature of the data, collecting relevant data, and integrating available datasets.
Data Preparation (PRP): Data are generally acquired in a raw format that needs certain preprocessing steps. This involves exploration and filtering, which helps identify the correct data for further processing. Well prepared data reduces the time required for data analysis and contributes to the success of the DS pipeline.
Storage (STR): It is important to find an appropriate hardware-software combination to preserve data so that it can be processed efficiently. For example, Miao et al. used graph database system Neo4j [44] to build a collaborative analysis pipeline [42], since Neo4j supports querying graph data properties.
Feature Engineering (FTR): The entire dataset might not contribute equally to decision making. In this stage, appropriate features that are useful to build the model are identified or constructed. Features that are not readily available in the dataset, require engineering to create them from raw data.
Modeling (MDL): When data are preprocessed and features are at hand, a model is built to analyze the data. Model building includes model planning, model selection, mining and deriving important properties of data. Appropriate data processing strategies and algorithms are selected to create a good model.
Training (TRN): For a specific model, we need to train the model with available labeled data. By each training iteration, we optimize the model and try to make it better. The quality of the training dataset contributes to the training accuracy of the model.
Evaluation (EVL): After training the model, it is tested with a new dataset which has not been used as training data. Also, the model can be evaluated in real-life scenarios and compared with other competing models. Existing metrics are used or new metrics are created to evaluate the model.
Prediction (PRD): The success of the model depends on how good a model can predict in an unknown setup. After a satisfactory evaluation, we employ the model to solve the problem and see how it works. There are many prediction metrics such as classification accuracy, log-loss, F1-score, to measure the success of the model.
Interpretation (INT): The prediction result might not be enough to make a decision. We often need a transformation of the prediction result and post-processing to translate predictions into knowledge. For example, only numerical results do not help much but a good visualization can help to make a decision.
Communication (CMN): Different components of the DS system might reside in a distributed environment. So, we might need to communicate with the involved parties (e.g., devices, persons, systems) to share and accumulate information. Communication might take place in different geographical locations or the same.
Deployment (DPL): The built DS solution is installed in its problem domain to serve the application. Over time, the performance of the model is monitored so that the model can be improved to handle new situations. Deployment also includes model maintenance and sending feedback to the model building layer.

Figure 4: Description of the stages in DS pipeline

RQ1b: What are the frequent and rare stages of the DS pipeline in theory? Among 46 DS pipelines (which are not team processes), Figure 5 shows the number of times each stage appears. *Modeling*, *data preparation*, and *feature engineering* appear most frequently. While *modeling* is present in 93% of the pipelines, other model related stages (*feature engineering*, *training*, *evaluation*, *prediction*) are not used consistently in the literature. Often *training* is not considered as a separate stage and included inside the *modeling* stage. Similarly, we found that *evaluation*, *prediction* are often not depicted as separate stages. However, separating the stages

Figure 5: Frequency of pipeline stages in theory

and modularizing the tasks, the DS process can be maintained better [4, 65]. The pipeline created with the most number of stages (11) is provided by Ashmore et al. [7]. On the other hand, about 15% of the pipelines from the literature are created with a minimal number (3) of stages. Among them, 80% are ML processes and falls in the category of DS optimizations. We found that these pipelines are very specific to a particular application, which include context-specific stages like data sampling, querying, visualization, etc., but do not cover most of the representative stages. Although each discussion of a DS pipeline in theory may not require all representative stages, comparative analysis could be facilitated by the use of a common architecture and terminology.

Finding 1: Post-processing layers are included infrequently (52%) compared to pre-processing (96%) and modeling (96%) layers.

Clearly, preprocessing and model building layers are considered in almost all of the studies. In most of the cases, the pipelines do not consider the post-processing activities (*interpretation*, *communication*, *deployment*). These pipelines often end with the predictive process and thus do not follow up with the later stages which entails how the result is interpreted, communicated and deployed to the external environment. Previous studies showed that significant amount of cost and effort is spent in the post-development phases in traditional software lifecycle [41, 55]. In data-intensive software, the maintenance cost can go even higher with the high-interest technical debt in the pipeline [64]. Therefore, post-processing stages should be incorporated for a better understanding of the impact of the proposed approach on maintenance of the DS pipeline.

2.3 Organization of Pipeline Stages in Theory

RQ2: How are pipeline stages connected to each other? In Figure 3, for simplicity, we depicted the DS pipeline as a mostly linear chain. However, our subject DS pipelines often have non-linear behavior. In any stage, the system might have to return to the previous stage for refinement and upgrade, e.g., if a system faces a real-world challenge in *modeling*, it has to update the algorithm which might affect the data pre-processing and feature engineering as well. Furthermore, the stages do not have strict boundaries in the DS lifecycle. In Figure 3, two backward arrows, from *feature*

engineering and *evaluation*, indicate feedback to any of the previous stages. Although in traditional software engineering processes (e.g., waterfall model, agile development, etc.), feedback loop is not uncommon, in DS lifecycle, there are multiple stakeholders and models in a distributed environment which makes the feedback loops more frequent and complex. Sculley et al. pointed that DS tasks such as sampling, learning, hyperparameter choice, etc. are entangled together so that changing anything changes everything (CACE principle) [65], which in turn creates implicit feedback loops that are not depicted in the pipelines [13, 21, 56, 72]. The feedback loops inside any specific layer are more frequent than the feedback loops from one layer to another. Also, a feedback loop to a distant previous stage is expensive. For example, if we do *data preparation* after *evaluation* then the intermediate stages also require updates.

2.4 Characteristics of the Pipelines in Theory

RQ3: What are the different types of pipelines available in theory? We classified each subject in our study into four classes based on the overall goal of the article. The most of the pipelines in theory (39%) are describing or proposing new pipelines to solve a new or existing problem. About 31% of the pipelines are on reviewing or comparing the existing pipelines. The third group of DS pipelines (14%) are intended to optimize a certain part of the pipeline. For example, Van Der Weide et al. proposes a pipeline for managing multiple versions of pipelines and optimize performance [72]. Most of the pipelines in this category are application specific and include very few stages necessary for the optimization. We observed that there is no standard methodology or framework to develop pipelines which might facilitate developing comparable and inter-operable DS pipelines. Using the labeling methodology shown in Figure 1, we labeled each pipeline and found three types of DS pipelines in the literature: 1) ML process, 2) big data management process, and 3) team process.

ML process: 46% of all the pipelines we found in the literature are describing machine learning processes. The recent advent of artificial intelligence, supervised learning and deep learning has led to more DS systems that involve ML components. The pipelines in this category emphasize the algorithmic process, learn patterns, and build model to make prediction. However, the post-processing stages are rare in these type of pipelines. The ML pipelines are often thought of as an algorithmic process in the laboratory scenario. But as mentioned in [7], incorporating the post-processing stages would be desired to ensure safe real-world deployment of such pipelines.

Big data management: The references in this category present DS pipelines that manage a large amount of data or describes a framework (software-hardware infrastructure) for data processing but do not contain machine learning components in the pipeline. Processing large amount data often requires specific algorithms and engineering methods for efficiency and further processing. We found that 18% of all the subject studies fall in this category.

Team process: We also found some DS pipelines that are not describing DS software architecture. These pipelines describe workflow of human activities that needs to be followed in a DS pipeline. These studies present a high-level view for building DS component in a team environment. The data science teams require specific

expertise and management to build successful DS pipelines [4, 39]. In this paper, in §3 and §4, we are only focusing on DS pipeline as software architecture, and therefore, we did not compare the team process pipelines in the rest of this section.

Finding 2: *Most of the pipelines involve cyber and physical components, only a few with human processes in the loop.*

We identified whether the pipelines involve cyber, physical or human process, using our labeling process described in section §2.1.2. **Cyber** processes refer to activities that involve automated systems and machinery computations. Since modern DS systems involves large amount of data and requires extensive computation, all of the pipelines include cyber component in it. **Physical** processes include the activities which require real-world connections with the system. For example, collecting data using mobile sensors or cameras is a physical process. Although 23% of the big data pipelines include physical processes, only 9% of the ML pipelines include that in the pipeline. In many DS systems, developers or researchers participate in the pipelines actively to make decisions that need **human** interventions [70, 72]. For example, in many DS systems, analytical model validation, troubleshooting, data interpretation is necessary which requires human involvement. However, only 13% of the pipelines acknowledged human involvement in the pipeline.

3 DS PIPELINE IN-THE-SMALL

Similar to the DS pipelines in large systems and frameworks, for a very specific data science task (e.g., object recognition, weather forecasting, etc.), programmers build pipeline. Different stages of the program perform a specific sub-task and connect with the other stages using data-flow or control-flow relations. In this section, we described such DS pipelines *in-the-small*. This analysis helped to understand the DS pipeline in practice.

3.1 Methodology

We collected 105 DS programs from Kaggle competition notebooks [32]. Kaggle is one of the most popular crowd-sourced platforms for DS competitions owned by Google. Besides participating in competitions, data scientists, researchers, developers collaborate to learn and share DS knowledge in variety of domains. The users and organizations can host a DS competition in Kaggle to solve real-world problems. A competition is accompanied by a dataset and prize money. Many Kaggle solutions have resulted in impactful DS algorithms and research such as neural networks used by Hinton and Dahl [15], improving the search for the Higgs Boson at CERN [30], etc. We chosen Kaggle solutions to analyze DS pipeline for three reasons: 1) all programs perform a complete DS task and provide solution to a well specified problem associated with a dataset, 2) the solutions with the highest number of votes are the most accepted solutions for a specific problem, and 3) the problems cover a wide range of domains.

There are 331 completed competitions in Kaggle to date. They categorized the competitions into *Featured*, *Research*, *Recruitment*, *Masters*, *Analytics*, *Playground* and *Getting started*. We collected solutions of all the competitions from each category except *Getting started* and *Playground* (these two categories are intended to serve as DS tutorials and toy projects). First, we filtered the competitions

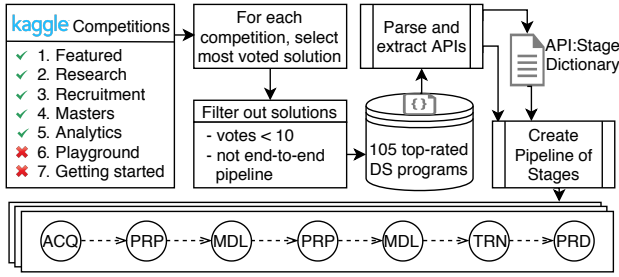

Figure 6: The pipeline creation process for Kaggle programs

for which there are solutions available (many old competitions do not contain any public solution). We found 138 such competitions. For a given competition problem, we selected the most voted solution which has at least 10 votes. Thus, we got 105 top-rated DS solutions for analyzing pipelines in-the-small. This selection and pipeline creation process is shown in Figure 6.

All of the DS programs are written in Python using ML libraries like Tensorflow, Keras, Scikit-learn, etc. These packages provide high-level Application Programming Interfaces (APIs) for performing a specific task on data or model. We parsed the programs into abstract syntax tree (AST) and collected all the API calls from the programs. The functionality of an API can characterize the stage of the pipelines the program is performing. We created a dictionary by mapping each API collected from the programs, to one of the 11 stages of the DS pipeline described in section §2. During the mapping, we excluded the generic APIs from the dictionary. For example, `model.summary()` is used to print the model parameters and does not represent any stage of the pipeline. For creating the dictionary, we taken a two-fold approach. First, we understand the context of the program and API usage. Second, we look at the API documentation to confirm the corresponding pipeline stage. This process was manually verified by two raters who labeled DS pipelines in section §2. Then, we built a tool which takes the API dictionary and DS program, and automatically creates the DS pipeline. For a sequence of APIs with the same stage, we abstracted them into a single stage. As an example, Figure 6 shows a DS pipeline created from a Kaggle solution [31]. Each stage in the pipeline (e.g., ACQ, PRP) represents one or more API usages. The arrows in the pipeline denote the temporal sequence of stages. Note that, one stage can appear multiple times in a pipeline. The API dictionary, Kaggle programs, and tool to generate the pipelines is shared in the paper artifact [5].

3.2 Representative Pipeline in-the-Small

RQ4: What are the stages of DS pipeline in-the-small? Among the 11 pipeline stages described in Figure 3, we found only 6 stages in the DS programs that are depicted in Figure 7. Other stages (e.g., storage, feature engineering, interpretation, communication, deployment) are not found in these programs because these stages occur while building a production-scale large DS system and often not present in the DS notebooks. Therefore, the pipeline in DS programs consists of the subset of pipeline stages in theory.

We summarized the frequency of each stage of the DS programs in Figure 8. Among 105 programs, data acquisition and data preparation are present in almost all of them. Surprisingly, modeling is

Figure 7: Pipeline in-the-small extracted from API usages.

Figure 8: Frequency of pipeline stages in DS programs

present in only 70% of the programs. We found that, in many programs, no modeling APIs had been used because developers did not use any built-in ML algorithm from libraries, e.g., LogisticRegression, LSTM, etc. In these cases, the developers use data-processing APIs on the training data to build custom model, e.g., this notebook [33] uses *data preparation* APIs to produce results. To enable more abstraction of the stages in these pipelines, further modularization is necessary, which has been investigated in RQ8.

Finding 3: Evaluation occurs only in 36% of the programs

Evaluation is a tricky stage of the DS pipeline. Developers have to choose the appropriate evaluation metric and methodology to evaluate their model. Based on the evaluation result, the model is updated over multiple iterations. We found that, besides using metrics, in many cases, evaluation requires human understanding and comparison of the result produced by the model. The reason for having less number of *evaluation* stage in the pipeline is that often the developers evaluate the performance by plotting and visualizing the result. Since the visualization APIs are not considered as *evaluation* stage, we found this stage less frequently in pipelines. Also, many programs directly go to the *prediction* stage without going to *evaluation* stage at all. Furthermore, notebooks are often used for experimentation purposes so that many computations are performed during development but eliminated when the notebooks are shared [37]. For example, one developer might try a number of classifiers and evaluate their accuracy. After finding the best performing classifier, it can be the only one shared in the notebook. Therefore, we experienced many missing stages in the pipeline in-the-small. The complex DS tasks require several computations which might not be used in producing the final prediction, but definitely should be considered as part of the pipeline.

3.3 Pipeline Organization in the Small

RQ5: How are the stages connected with each other in pipeline in-the-small? To answer RQ5, we considered each occurrence of the stages in a DS program and looked at its previous and next stage. In Figure 9, we showed which stages are followed or preceded by each stage. We found that *data preparation* can occur before or after all other stages. Apart from that, *data acquisition* is followed by *data preparation* most of the time, which in turn is followed by *modeling*. *Modeling* is followed mostly by *training*, which in turn is followed by *prediction*. *Evaluation* is mostly surrounded by *prediction* and *data preparation*. From Figure 9, we can also find some

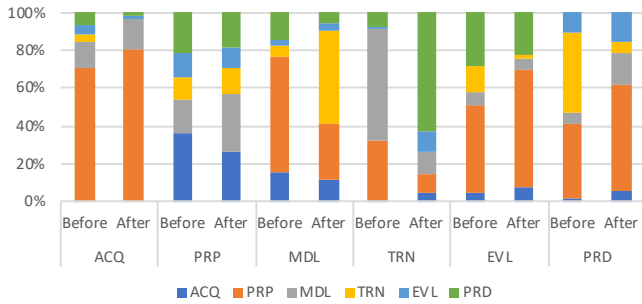

Figure 9: Stages occurring before and after each stage

most occurring feedback loop: *evaluation to preparation, evaluation to modeling and prediction to modeling*.

Data preparation tasks (e.g., formatting, reshaping, sorting) are not limited to just before the modeling stage, rather it is done on a *whenever-needed* basis. For example, in the following code snippet from a Kaggle competition [34], while creating model-layers, data preprocessing API has been called in line 2.

```
1 x = Conv2D(mid, (4, 1), activation='relu', padding='valid')(x)
2 x = Reshape((branch_model.output_shape[1], mid, 1))(x)
3 x = Conv2D(1, (1, mid), activation='linear', padding='valid')(x)
4 x = Flatten(name='flatten')(x)
5 head_model = Model([xa_inp, xb_inp], x, name='head')
```

The modeling stage is always surrounded by other stages of the pipeline. However, there is often a loop around *modeling, training, evaluation, and prediction*. Modeling often repeats many times to improve the model over multiple iterations. For example, in the following Kaggle code snippet [35], the model is created and trained multiple times to find the best one.

```
1 #Modeling
2 random_forest = RandomForestClassifier(n_estimators=100,
3                                     random_state=50, verbose=1, n_jobs=-1)
4 # Train and prediction
5 random_forest.fit(train, train_labels)
6 ...
7 poly_features = scaler.fit_transform(poly_features)
8 poly_features_test = scaler.transform(poly_features_test)
9 # Modeling
10 random_forest_poly = RandomForestClassifier(n_estimators=100,
11                                           random_state=50, verbose=1, n_jobs=-1)
12 # Training and prediction
13 random_forest_poly.fit(poly_features, train_labels)
14 pred = random_forest_poly.predict_proba(poly_features_test)[: ,1]
```

Finding 4: Pipeline stages are often tangled with each other.

All of the DS programs fail to maintain a good separation of concerns [17] between stages. Strong abstraction boundaries help to make the program modular and easy-to-maintain [50]. In addition, a good DS solution should not only compute a better prediction result, but also facilitate software engineering activities (e.g., debugging, testing, monitoring, etc.) [25]. However, we found that stages are often *tangled* with other stages [12, 38, 53] across the pipeline. The code for one stage is interspersed with the code for other stages. For example, while building the deep learning network (*modeling*), the developers often switch to different *data preparation* tasks, e.g., reshaping, resizing [29], which tangles data preparation concern with the modeling concern. We observed some early attempts to adopt modular design practices. For instance, this notebook [36] separated code into different high-level stages, namely, preparation,

feature extraction, exploratory data analysis (EDA), topic model, etc. These high-level pipelines can improve the abstract boundary, which further improves the readability and maintainability of DS programs [60]. But, more attention on modular design practices is needed for DS pipeline.

Finding 5: Data preparation stage is occurring significant number of times in between any two stages, which is causing pipeline jungles.

We found that new data sources are added, new features are identified, and new values are calculated incrementally in the pipeline which evolves organically. This results in a large number of data preprocessing tasks like sampling, joining, resizing along with random file input-output. This is called *pipeline jungles* [65], which causes technical debt for DS systems in the long run. *Pipeline jungles* are hard to test and any small change in the pipeline will take a lot of effort to integrate. The situation gets worse in case of larger DS pipelines. The recommended way is to think about the pipeline holistically and scrape the pipeline jungle by redesigning it, which in turn takes further engineering effort [65]. We found that the large DS projects, which are discussed in §4, isolate the data preparation tasks into separate files and modules [11, 62, 71, 80], which alleviates the pipeline jungles problem. So, DS pipeline in-the-small needs further IDE (e.g., Jupyter notebook, etc.) support and methodologies for code isolation and modularization.

3.4 Characteristics of Pipelines in-the-Small

RQ6: What are the patterns in pipeline in-the-small and how it compares to pipeline in theory? We have not found many stages from Figure 3, e.g., feature engineering, interpretation, communication, in pipeline in-the-small. One reason is the low-level pipeline extracted from the API usages cannot capture some stages. For example, even if a developer is conducting feature engineering, the used APIs might be from the data preparation stage. Fortunately, we found many Kaggle notebooks are organized by the pipeline stages. We visited all the 105 Kaggle notebooks in our collection and extracted these high-level pipelines manually. Unlike the low-level pipelines (extracted using API usages), a high-level pipeline consists of the stages abstracted by the developers and specified in the notebooks.

The Kaggle notebooks follow literate programming paradigm [60, 74], which allows the developers to describe the code using rich text and separate them into sections. We found that 34 out of 105 notebooks divided the code into stages. We collected those stages from the Kaggle notebooks. Furthermore, we labeled these notebooks into the 11 stages from DS pipeline in theory by two raters, and extracted the stages that are not present in theory. The extracted high-level pipelines and labels are available in the paper artifact [5].

We observed that no notebooks specify these stages: *storage, interpretation, communication, and deployment*. These DS programs are not production-scale projects. Therefore, they do not include the post-processing stages in the pipeline. The most common stages are *modeling* (79%), *data preparation* (62%), *data acquisition* (53%), and *feature engineering* (35%), which is aligned with the finding of DS pipeline in theory. In addition, we have these stages which are not present in DS pipeline in theory: *library loading, exploratory data analysis (EDA), visualization*. Among them *EDA* has been used most

Figure 10: Representative data science pipeline *in-the-small*

of the times, i.e., 43% of the pipelines. In these notebooks, *EDA* has covered the most part of the pipeline. Before going to the modeling and successive stages, a lot of effort is given on understanding the data, compute feature importance, and visualize the patterns, since these steps help to build effective model quickly in the later stages.

Furthermore, some notebooks present *library loading* as separate stage. We observed that choosing appropriate library/framework and setting up the environment is an important step while developing pipeline in-the-small. We also found that data visualization is an recurring stage mentioned by the developers. Visualization can be done before modeling, for EDA or feature engineering purpose or after modeling, for evaluation and model improvement purpose. Based on these observations we updated the representative pipeline in-the-small in Figure 10. The high-level pipeline provides an overall representation of the system, which can be leveraged to design software process. It would be beneficial for the developers to close the gap between the low-level and the high-level pipeline by identifying the tangled stages.

4 DS PIPELINE IN-THE-LARGE

The DS solutions described in the previous section are specific to a given dataset and a well-defined problem. However, there are many DS projects which are large, not limited to a single source file, and contains multiple modules. These solutions are intended to solve more general problems which might not be specific to a dataset. For example, the objective of the *Face Classification* project in GitHub [6] is to detect face from images or videos and classify them based on gender and emotion. This problem is not specific to a particular dataset and the scope is broader compared to the Kaggle solutions. We have collected such top-rated DS projects from GitHub to analyze DS pipeline in-the-large.

Figure 11: Pipeline creation process for GitHub projects

4.1 Methodology

Biswas et al. published a dataset containing top rated DS projects from GitHub [10]. From the list of projects in this dataset, we have filtered mature DS projects having more than 1000 stars. Thus, we have found 269 mature GitHub projects. However, there are many projects in this list which are DS libraries, frameworks or utilities. Since we want to analyze the pipeline of data science software, we have removed those projects. Finally, we have also removed the repositories which serve educational purposes. Thus, we have found a list of 21 mature open-source DS projects. The list of projects, and their purpose are shown in Table 1.

For each project, we have created two pipelines: high-level pipeline and low-level pipeline. For creating the high-level pipeline, we have manually checked the project architecture, module structure and execution process. This gave us a good understanding of the source file organization and linkage between modules. After identifying the high-level pipeline and execution sequences of the source files, we have used the same API based method used to analyze Kaggle programs in the previous section, to create low-level pipeline of these GitHub projects. The methodology of selecting and extracting pipelines from the GitHub projects is shown in Figure 11.

For example, the project *QANet* [80] is intended to do machine reading comprehension. Here, Python has been used as the primary language, and shell script has been used for data downloading and project setup. The high-level pipeline for *QANet* includes the stages: *data acquisition*, *data preparation*, *modeling*, *training*, *evaluation* and *prediction*. In the beginning, `config.py` file integrates the modules (preparation, modeling, and training) and provides an interface to configure a model by specifying dataset and other parameters. Then, the file `evaluate.py` is executed to perform the evaluation and prediction. For the low-level pipeline, for a specific file, we used the API based analysis to generate the pipeline, which was used to analyze pipeline in-the-small. For instance, in the project *QANet*, although `model.py` serves modeling at a high level, it also does data preparation, training, and evaluation, when APIs are considered. In addition to the pipeline stages, we have also identified a few other properties of each project: 1) number of contributors, 2) AST count, 2) technology/language used, 3) entry points and 4) execution sequence. We have leveraged the Boa infrastructure [18] to analyze the different properties of the projects. These properties helped us to categorize and analyze the pipeline in-the-large. The details of the projects are available in the paper artifact [5].

The projects are from various domains: object detection, face classification, automated driving, speech synthesis, number plate recognition, predict time series sequence, etc. The number of developers in each project ranges between 1 and 40 with an average of 8. Among 21 projects, 16 of them are developed by teams and 5 of them are developed by individuals. The primary language used to develop these projects is Python.

4.2 Representative Pipeline in-the-Large

Compared to the Kaggle programs, we have found a significant difference in the pipeline of large DS projects. Because of the larger size of the projects, the pipeline architecture is different. All the projects contain multiple source files for handling different tasks (e.g., modeling, training) and about 50% of the projects organize the source files into modules (e.g., *utils*, *preprocessing*, *model*, etc.).

RQ7: What is the representative DS pipeline in-the-large? Each of the projects contains six stages described in Figure 7: *acquisition*, *preparation*, *modeling*, *training*, *evaluation*, and *prediction*. However, since the projects are not coupled to a specific dataset and they solve a more general problem, the projects are not limited

Table 1: GitHub projects for analyzing pipeline in-the-large.

Project Name	Purpose	# Files	# AST	LOC
Autopilot [3]	Pilot a car using computer vision	36	11185	348
CNN-Text-Classification [11]	Sentence classification	69	47797	11.4K
Darkflow [71]	Real-time object detection and classification	1025	655670	8.6K
Deep ANPR [19]	Automatic number plate recognition	64	70464	10.8K
Deep Text Corrector [48]	Correct input errors in short text	47	50770	3.0K
Face Classification [6]	Real-time face and emotion/gender detection	292	117901	35.3K
FaceNet [62]	Face recognition	1352	1889529	18.2K
KittiSeg [69]	Road segmentation	276	187143	4.8K
LSTM-Neural-Network [8]	Predict time series steps and sequences	24	11434	1.2K
Mask R-CNN [2]	Object detection and instance segmentation	256	1567786	15.6K
MobileNet SSD [54]	Object detection network	28	21272	25.6K
MTCNN [14]	Joint face detection and alignment	153	121138	219.7K
Object-Detector-App [16]	Real-time object recognition	215	318534	47.9K
Password-Analysis [61]	Analyze a large corpus of text passwords	148	67870	3.6K
Person Blocker [79]	Block people in images	12	44517	977
QANet [80]	Machine reading comprehension	83	107669	2K
Speech-to-Text-WaveNet	Sentence level english speech recognition	32	18626	5.1K
Tacotron [49]	Text-to-speech synthesis	114	58845	1.4K
Text-Detection-CTPN [59]	Text detection	640	257083	18.4K
TF-Recomm [68]	Recommendation systems	17	7789	535
XLNet [81]	Language understanding	36	143172	11.5K

to one single pipeline. We have found that the pipeline of each project is divided into two phases: 1) development phase and 2) post-development phase, which is depicted in Figure 12.

In **development phase**, the main goal is to build a model that solves the problem in general. A base dataset is used to build the model that would be used for other future datasets. After completing a *modeling, training, evaluation* loop, the final model is created and saved as an artifact. After creating the model artifact, the projects also create model interfaces, which lets the user modify and exploit the model in the post-development phase. Finally, the model artifact is saved as a source file or some model archiving formats. For example, the project *Person-Blocker* [79] and *Speech-to-Text-WaveNet* [40] saved the model in the source file (`model.py`) and lets the users train the model in the next phase. On the other hand, the project *KittiSeg* [69] and *Autopilot* [3] saved the built model artifact in JSON format (`.json`) and checkpoint format (`.ckpt`) respectively. We have observed that the evaluation and prediction is often not the main goal in this phase. Rather, building an appropriate model and making it available for further usage is the central activity in the development phase.

In **post-development phase**, the users access the pre-built model and use that for prediction. After acquiring data, a few pre-processing steps are needed to feed the model. In all of the projects under this study, we have found that the development phase is similar. However, we have identified three different patterns in the post-development phase which are shown in Figure 12. First, the users can modify the model by setting its hyperparameters and use that to make prediction on a new dataset. Second, the users can use the model as-it-is and train the model on the new dataset to make prediction. Third, the users can also download the pre-trained model and directly leverage that for prediction. Finally, at the end of this phase, the prediction result is obtained.

The post-development phase in the pipeline enabled software reusability of the models. All of these projects have instructions in their readme or documentation explaining the usage and customization. For example, the project *Deep ANPR* [19] provides instructions for obtaining large training data, retraining the models, and build it for prediction. However, not all the projects enable reusability in the development pipelines. Only a few of them provides access to the modules by importing in new development scenario. For

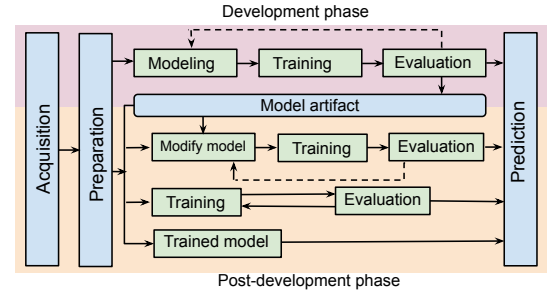

Figure 12: DS pipeline in-the-large. Development phase (top) runs during model building and post-development phase (bottom) runs for making prediction.

instance, *Darkflow* [71] let users access the `darkflow.net.build` module and use it in new application development. To increase the reusability of DS programs, it would be desired to consider similar access to the development pipeline of these large projects.

4.3 Organization of DS Pipeline in-the-Large

RQ8: How are the stages connected in pipeline in-the-large?

The abstraction in DS projects is stricter than the DS programs described in §3. The projects are built in a modular fashion, i.e., one source file for a broad task (e.g., `train.py`, `model.py`). However, inside one specific file, there are many other possible stages, especially data *preprocessing* appears inside all the source files. In addition, the module connectivity is not linear. All of the modules use external libraries for performing different tasks. As a result, there are a lot of interdependencies (both internal and external) in the DS pipeline. One immediate difference of these pipelines with traditional software is DS pipelines are heavily dependant on the data. For example, the project *Speech-to-Text-WaveNet* [40] requires a certain format of data. When we want to use that in a new situation, the data properties might be different. So, the usage pipelines would have a few additional stages. In some cases, the original pipeline is modified. Here, there are many sub-pipelines work together to build a large pipeline. However, we have not found any framework or common methodology these software are using. The different patterns of DS pipelines seek more advanced methodology or framework to build DS pipeline and release for production.

4.4 Characteristics of Pipelines in-the-Large

RQ: What are the patterns found in the pipelines?

The pipelines found in this setting can be categorized into 1) loosely coupled and 2) tightly coupled based on their modularity in the pipeline. A high number of contributors in the project resulted in a more modular and loosely coupled pipeline. We found the Loosely coupled ones are designed in a modular fashion so that one module (e.g., data cleaning, modeling) is built in such a way that it can be used by other modules as a library functionality. These modules accept the parameters as inputs and executed in an *as-needed* basis in the DS pipeline. Usually, there are multiple entry-points in a loosely coupled pipeline and user has more flexibility using the software. On the other hand, in a tightly coupled pipeline, the modules are stricter and integrated with other modules tightly in the software.

There is only one or two entry-points to the pipeline, which automatically calls the modules sequentially. We have found that the projects with 6 or more contributors (~75%) have followed a loosely coupled architecture and projects with 1 to 5 contributors have followed tightly coupled architecture.

Finding 6: *There is no common tool for pipeline integration and deployment.*

Although all the project under this study are written using Python, there is no common tool that integrates the DS modules and provides interface to the pipeline. Today, continuous integration and deployment (CI/CD) tools are used as a common practice in traditional software lifecycle to automate compilation, building, and testing [26]. We have found some CI/CD tools that integrate ML pipelines in our subject studies from pipeline in-theory [27, 43, 45]. However, we found no projects in pipeline in-the-large are using any CI/CD tools. In most cases, the environment setup and access to functionalities are done manually with command lines [3, 59]. Some projects have used *docker container* [6, 40, 62, 79] to set up the environment and run the pipeline. A few others have used Python notebooks to call different modules to integrate the pipeline stages [2, 16, 48]. 7 out of 21 projects used shell script for integration (e.g., sending HTTP request to download data, model reuse, etc.) [54, 80]. Further research is needed to investigate the challenges of using CI/CD in data science projects.

5 THREAT TO VALIDITY

For building the pipelines from the DS programs, we relied on the APIs. One threat might be, what happens if the developer does not use any API for completing a stage in the program. We have examined this possibility and found that DS programs are heavily dependent on libraries and external APIs and ML tasks are always performed using library APIs. Additionally, we have validated the API-to-stage dictionary with the API documentation and manual verification.

Another possible threat is that the Kaggle solutions might not be representative. We have taken a two-fold strategy to mitigate that threat. First, we have selected the solutions with the most number of votes and at least 10 votes. Second, we have manually verified each program whether it is an end-to-end DS solution. Since some most voted solutions are only for introduction and exploratory analysis of the dataset, by manual verification, we have excluded those programs. The GitHub projects are also taken from a previously published dataset containing DS repositories. We have further filtered them based on the number of stars and whether they perform a DS task.

Moreover, since the chosen DS programs from Kaggle and GitHub are using Python as the primary language, another question might be on the generalization of them as DS programs. According to GitHub and *Stack Overflow*, Python has become the most growing language in recent times [28, 57]. In data science, Python is the most used language because of the availability of numerous ML, DL and data analysis packages such as Pandas, NumPy, TensorFlow, Keras, Caffe, Theano, Scikit-Learn and many more.

6 RELATED WORK

Many studies presented ML pipeline in their own context, which can not be generalized for all DS systems. Garcia et al. [22] focused on building an iterative process with three main phases: development, training and inference. They described the interpretation of data and code while integrating the whole lifecycle. Polyzotis et al. [51] presented the challenges of data management in each stage of a production ML pipeline and encouraged further research in the area. In another paper, Polyzotis et al. [52] presented challenges of building large ML platform in Google (e.g., TensorFlow) around three broad themes: data understanding, data validation and cleaning, and data preparation. They also provided an overview of and end-to-end large-scale ML pipeline with a data point of view. Carlton E. Sapp defined ML concepts, its business challenges, stages of the ML lifecycle, data science team and their roles, and comprehensive end-to-end ML architecture [63]. This gives us a holistic understanding of the business processes (e.g., acquire, organize, analyze, deliver) of a data science project.

A few other studies try to capture the DS process by surveying and interviewing developers. Roh et al. [58] surveyed the data collection techniques in the field of big data. They presented the workflow of data collection answering how to improve data or models in an ML system. Another study [4] identified the software engineering practices and challenges in building AI applications and DS tools inside Microsoft development teams. They found some key differences in software process in AI compared to other domains. They have considered a 9-stage workflow for DS software development. Hill et al. [25] interviewed experienced AI developers and identified problems they face in each stage. They tried to compare the traditional software process and the AI process. Zhou presented her own view to build a better ML pipeline [82]. They presented three challenges in building ML pipelines: data quality, reliability and accessibility. Some articles described ML applications and frameworks which present DS pipelines from the industry. For example, *Databricks* [27] provides a set of high-level APIs for programming languages. Team Data Science Process (TDSP) is an agile and iterative process to build intelligent applications inside Microsoft corporation [66]. In a US patent [70], the authors compared two data analytic pipelines. They presented the difference in the set of parameters in terms of time and cost of those two lifecycles. Cross Industry Standard Process for Data Mining (CRISP-DM) [78] is a 6-stage comprehensive process model for data mining projects across any industry. Google Cloud Blog [24] described an ML workflow, which is provided by an AI platform. They explained tasks completed in each stage with respect to Google Cloud and TensorFlow[1].

Although there are many papers in the literature presenting DS pipeline, there is no comprehensive study that tries to understand and compare data science pipelines in theory and practice.

7 CONCLUSION

Many software systems today are incorporating a data science pipeline as their integral part. In this work, we argued that to facilitate research and practice on data science pipelines, it is essential to understand their nature. To that end, we presented a three-pronged

comprehensive study of data science pipelines in theory, data science pipelines in-the-small, and data science pipelines in-the-large. Our study analyzed three datasets: a collection of 71 proposals for data science pipelines and related concepts in theory, a collection of 105 implementations of data science pipelines from Kaggle competitions to understand data science in-the-small, and a collection of 21 mature data science projects from GitHub to understand data science in-the-large. We have found that DS pipelines differ significantly between these settings. Specifically, a number of stages are absent in-the-small, and the DS pipelines have a more linear structure. The DS pipelines in-the-large have a more complex structure and feedback loops compared to the theoretical representations. We also contribute three representations of DS pipelines that capture the essence of our subjects in theory, in-the-small, and in-the-large.
